A WEEKLY REVIEW OF MEDICINE

VOLUME CXII.

JULY TO DECEMBER, 1920, INCLUSIVE.

NEW YORK

A. R. ELLIOTT PUBLISHING CO.

1920

LIST OF ILLUSTRATIONS TO VOLUME CXII

	Page
Abdominal exercises before and after delivery. Four Illustrations.	722-723
Amputation of the cervix uteri. Two Illustrations.	711
Asthma, diagnostic tests in. Six Illustrations.	112
Benzyl benzoate in circulatory conditions. One Illustration.	270
Bodies, foreign, in bronchi and esophagus. Fifty-two Illustrations.	654-665
Carcinoma of middle ear. Two Illustrations.	675
Cervical laceration, cystocele, prolapsus uteri, and multiple fibromata. Three Illustrations.	714-715
Congenital megacolon (Hirschsprung's disease). Two Illustrations.	1030-1031
Cutaneous anthrax. Two Illustrations.	931
Dental infection. Four Illustrations.	354, 355, 356
Diseases of the cervix uteri. Seven Illustrations.	707-709
Empyema in children. One Chart.	987
Eye, choked disc of, unilateral. Two charts.	157
Female pelvic ureters. One Illustration.	721
Fissure fracture of the tibia. Two Illustrations.	365
Gallbladder affections, diagnosis and treatment of. Three Illustrations.	2
Gastric superacidity. One Illustration.	5
Gastrointestinal conditions, diagnostic charts in. Four Illustrations.	125
Hay fever, diagnostic tests in. Six Illustrations.	112
Hirschsprung's disease. Two Illustrations.	1030
Historical notes on the practice of medicine in New York City. Two Illustrations and Three Portraits.	350, 351, 352
Infant mortality in United States birth registration area. One Illustration.	1010
Infections of hand and their surgical treatment. Seven Illustrations.	669
Instrument for simplifying tonsillectomy. One Illustration.	681
Posture, good, underlying factors in. Three Illustrations.	81
Protein fever. Five Charts.	32-327
Röntgen dose estimation. Fifteen Illustrations.	93
Salvarsan administered by rectum in the form of enteroclysis. One Illustration.	275
Stereoscopic campimeter slate. Four Illustrations.	94
Surgical mensuration, standardization of. Nine Illustrations.	110
Typhoid fever epidemic. One Chart.	149
Ulcer, peptic. Nine Illustrations.	117
Underdevelopment, congenital. Two Illustrations.	678
Weak foot in child. Ten Illustrations.	98
Xeroderma pigmentosum. Two Illustrations.	98
X ray an essential guide for producing artificial pneumothorax in pulmonary tuberculosis. Seven Illustrations.	673

LIST OF CONTRIBUTORS TO VOLUME CXII.

Those whose names are marked with an asterisk have contributed editorial articles.

- ABBOTT, GEORGE KNAPP, A. B., M. D., Sanitarium, Cal.
- APPEL, H., M. D., Brooklyn, N. Y.
- *ARROWSMITH, HUBERT, M. D., F. A. C. S., Brooklyn, N. Y.
- BALL, CHARLES R., M. D., St. Paul, Minn.
- BANDLER, SAMUEL W., M. D.
- BARNES, GEORGE EDWARD, M. D., Herkimer, N. Y.
- BARR, MARTIN W., M. D., Elwyn, Pa.
- BANGERT, GEORGE SCHUYLER, Ph. G., M. D., East Orange, N. J.
- BARACH, JOSEPH H., M. D., Pittsburgh, Pa.
- BASCH, SEYMOUR, M. D.
- BASSLER, ANTHONY, M. D.
- BATES, W. H., M. D.
- BEATES, HENRY, JR., M. D., Sc. D., Philadelphia.
- BEHREND, MOSES, M. D., Philadelphia.
- BLAND, P. BROOKE, M. D., F. A. C. S., Philadelphia.
- BLAU, ARTHUR I., M. D.
- BLAUNER, SAMUEL A., M. D.
- BLODGETT, STEPHEN H., M. D., Boston.
- BOLDUAN, CHARLES F., M. D., Washington, D. C.
- BREWER, ISAAC W., M. D., Watertown, N. Y.
- BRINK, LOUISE, A. B.
- BROWN, ALEXANDER A., M. D., San Antonio, Tex.
- ADWALLADER, JOSEPH M., A. M., M. D., San Antonio, Tex.
- ARTER, C. EDGERTON, M. D., Los Angeles, Cal.
- CHURCH, JAMES ROBB, M. D., Colonel, Medical Corps, United States Army, Washington, D. C.
- LEMONS, E. JAY, M. D., Los Angeles, Cal.
- LOUTING, CHARLES A., M. D., London.
- DOOPER, NAVROJI A., M. D., Bombay, India.
- ARNWALL, LEON H., M. D.
- OTT, GEORGE F., M. D., Buffalo.
- OSTER, LAWRENCE H., M. D.
- UGHLIN, WILLIAM T., M. D., F. A. C. S., St. Louis, Mo.
- WAMPTON, C. WARD, M. D., Battle Creek, Mich.
- WAWFORD, JAMES P., M. D., San Francisco.
- WUCHET, RENÉ, M. D., Bordeaux, France.
- WYMMING, HUGH S., M. D., Surgeon General, United States Public Health Service, Washington.
- CUMMINGS, W. CLOVIS, M. D., Oklahoma City, Okla.
- *CUMSTON, CHARLES GREENE, M. D., Geneva, Switzerland.

INDEX TO VOLUME CXII.

	PAGE.		PAGE.
A BBOTT, George Knapp. Periodical headaches of ovarian origin.....	724	Animals, lower, comparative anatomy of genitourinary organs of.....	525
Abdomen, acute, treatment of.....	233	Anomalies, anatomical, clinical importance of, in biliary surgery.....	473
disorders of, acidosis in.....	42	Anteflexion, acute, of uterus.....	703
tender points in, percussion of.....	42	Anthrax, cutaneous.....	931
Abdominal cyst, unusual.....	743	human, treatment of, by normal bovine serum.....	692
exercises.....	854	meningitis, primary.....	604
before and after delivery, value of.....	722	transmission of, from shaving brush.....	604
incisions.....	235	Antiseptic, chlorine.....	472
noninfected, syphilis as cause of delayed healing in.....	539	Antitoxin administration in diphtheria 783.....	871
relaxation, rhythmic electric currents in treatment of.....	441	Aorta, rupture of.....	547
section, suppurating wounds following.....	606	Aortic regurgitation, venesection in.....	901
symptoms in influenza simulating surgical lesion.....	216	Aortitis, specific.....	559
viscera, disorders of.....	752	Apoplexy, thyroid, tetany in adult due to.....	739
Abduction treatment of fracture of neck of femur.....	651	Appel, H. Lumbar puncture in diseases of children.....	1021
Abnormalities, with congenital absence of vagina.....	742	Appendectomy, late results of.....	40
Abortion, missed.....	829	volvulus complicating.....	22
treatment of, complicated by sepsis.....	829	Appendicitis, chronic, operations for.....	42
Abscess of liver.....	872	Appendix, diseases of.....	94
peritonissilar, chronic.....	193	Arbutnot, Dr. John—physician author.....	551
pulmonary, x ray in.....	841	Aristotle, theory of pneumonia in.....	833
Absence of vagina, congenital, with other abnormalities.....	742	Army, United States, influenza in.....	342
Abscesses, multiple, of brain.....	605	Arrhythmia.....	288
unopened mammary, aspiration and pressure treatment of.....	735	Arsenic, colloidal, in influenza.....	648
Absorption of membranous bones.....	1051	poisoning following salvarsan administration.....	559
Acacia, gum, action of, on circulation.....	692	Arsenical products, ocular accidents attributed to.....	506
Acid, chronic, in suppurative dacryocystitis.....	827	Arsphenamine, intensive administration of reactions following intravenous administration of.....	498
phenylacetic, toxicity of.....	383	toxicity of.....	516
picric, use of, in preparing skin for operation.....	829	trypanocidal activity of.....	515
salicylic, hypodermic injections of, in gout and rheumatism.....	691	Arterial fibrosis, hypertension in relation to hypertension, treatment of.....	152
Acidity, gastric, excess of.....	5	Arteriosclerosis, etiology and symptomatology of.....	605
Acidosis.....	256	gastrointestinal infections in relation to.....	13
history of.....	246	Arteriovenous fistula, effect of, upon heart and bloodvessels.....	960
in acute abdominal disorders.....	42	Arthritic cellulitis, treatment of.....	375
Accidental hemorrhage.....	742	Arthritis, chronic, distant foci of infection in.....	108
Accidents from ladders.....	597	following ingestion of hexamethylenamine.....	560
Acne, x ray treatment of.....	839	multiple, complicating lobar pneumonia treatment of prostate in.....	161
Action of digitalis, effect of high temperature upon.....	782	of seminal vesicles in.....	652
Acute encephalitis in children.....	739	Arthrodesis for nontuberculous hip joint.....	828
Adenitis, venereal, injections of milk in treatment of.....	496	Arthroplasty of knee joint.....	828
x ray in.....	842	Artillery fire, lethal aspects of.....	784
Adenoiditis, acute, in children.....	638	Asexualization, report of eighteen cases of hypertension, treatment of.....	500
Adenomata, thyroid toxic, mild types of.....	695	Aspiration and pressure treatment of unopened mammary abscesses.....	735
Adenomyomata, submucous.....	742	Association, free, and its right to use.....	862
Adenopathy, tracheobronchial, diagnostic signs in.....	1047	Asthma, bronchial, in childhood.....	399
Adolescence, autoerotic phenomena in.....	334	protein sensitization in.....	108
Adrenalin injections, effect of, upon blood pressure in dementia præcox.....	691	diagnostic tests in.....	112
modification of action of, by chloroform.....	1047	problem.....	392
Aftertreatment in surgical cases.....	1048	treatment of, with benzyl benzoate by injection.....	403
Age, old, mental disorders of.....	604	Astigmatism, cause of.....	816
Alcoholism and tuberculosis.....	876	disturbances of heart and liver caused by low grades of.....	447
Alkali tolerance test, Sellard's.....	256	Asylums, lunatic, inmates of.....	420
Alkalosis, unusual case of, with impairment of excretory power of kidneys.....	966	Ataxia, cerebocerebellar, acute.....	1007
American Revolution, medical men in.....	345, 410, 455,	Atropine, use of, in treatment of hypertonic infant.....	971
amniotic hernia.....	737	Auræ, a consideration of the nature of.....	342
amputation of cervix uteri.....	710	Aural suppurations coupled with syphilis, intracranial complications in.....	341
of leg.....	233	Auricle, involvement of, and conduction pathways of heart following influenza.....	873
tissue sparing, of foot.....	428	Autohemotherapy in protracted infections.....	692
analgesia, postoperative.....	903	Azotemia, with chronic nephritis, intravenous injection of hypertonic glucose solution in.....	471
spinal.....	300	B ACILLARY dysentery, complications of.....	1046
in labor.....	562	in children.....	1046
naphylactic manifestations, new method of preventing.....	693	Bacillus, colon.....	522
shock, simple means of obviating.....	1048	in kidney infections.....	652, 694
anatomical anomalies, clinical importance of, in biliary surgery.....	473	Backache from viewpoint of general surgeon.....	1005
theories of Plato.....	141	409	409
anatomy, comparative, of genitourinary organs of lower animals.....	525	Bacteriology of colitis.....	1005
nemia, pernicious.....	359	Ball, Charles R. Doctor and neuropath.....	575
secondary types of.....	360	Bandler, Samuel W. Placental gland and placental extract.....	745
splenic.....	360	Bangert, George Schuyler. Seven generations of physicians.....	277
and Banti's disease.....	305	Banti's disease and splenic anemia.....	305
nemias, relationship of, to life insurance nesthesia.....	358	Barach, Joseph H. Cholesterol thorax.....	811
ether oil colonic, in treatment of toxic thyroid.....	315	Barium chloride and cardiac inhibition.....	781
thyroid.....	744	Barnes, George Edward. Cause of astigmatism.....	816
ethyl chloride, brief or prolonged.....	339	Barr, Martin W. Observations on the stigmata of degeneration as found in the feeble-minded.....	80
general.....	472, 693		
in labor.....	562		
local, combined with morphine and scopalamine narcosis, in Cesarean section.....	339		
in rectal surgery.....	339		
with ethyl chloride in fractional amounts.....	233		
nesthetic, local, action of saligenin as.....	693		
benzyl carbinol as.....	339		
nesthesics in shock.....	338		
neurysms, formation of in acute endoarteritis.....	547

THE DIAGNOSIS AND TREATMENT OF GALLBLADDER AFFECTIONS.*

BY MAX EINHORN, M. D.,

New York,

Professor of Medicine at the New York Postgraduate Medical School; Visiting Physician to the Lenox Hill Hospital, New York.

In a paper on Ischochymia Simulating Gallstone Disease (1), published a number of years ago, I presented reports of several cases in which the patients had had typical attacks of what was apparently gallstone colic, some with slight jaundice. The real trouble, however, was not in the gallbladder, but in the pylorus or the duodenum. Later I described a case (2) of duodenal ulcer, in which the symptoms and previous treatment for many years had been those of distinct cholelithiasis. In this patient the newer methods of diagnosis indicated that we had to deal with a duodenal ulcer. An operation disclosed the presence of the ulcer but failed to find any abnormal condition of the gallbladder. It is thus evident that a correct diagnosis in gallbladder lesions is not always an easy matter, and their characteristic symptoms are sometimes misleading. I thought, therefore, it would be of interest to broach the subject of gallbladder affections.

Almost all gallbladder diseases are intimately connected with gallstones; either they predispose to the formation of the latter, or the calculi are the cause of the lesion. It will, therefore, be appropriate to state a few well known facts regarding gallstones. The formation of gallstones is due, according to Naunyn, to bacterial infections of the gallbladder. Aschoff and Bacmeister (3) accept this view in a general way, but mention that some cholesterol stones originate without the aid of bacteria, but are solely due to stagnation of bile in the gallbladder.

Gallstones are found in ten per cent. of all autopsies performed in adults. Not all gallstone carriers, however, manifest morbid symptoms. It is generally assumed by clinicians that about five per cent. of these carriers at one time or another are troubled with mild or severe lesions, due to the biliary calculi. Kehr, one of the greatest gallbladder surgeons, maintains that but one per cent. of the gallstone carriers ultimately require surgical aid to remedy the gallstone disease. In contrast to this

view a great many surgeons believe that all gallstones are pathological and accompanied by symptoms, which are frequently not recognized. Gallstones are much more frequently found in women than in men, and principally in women who have gone through pregnancies.

After these preparatory remarks, returning to the diseases of the gallbladder, we can practically divide them as follows: 1, Acute cholecystitis, without and with jaundice; 2, chronic or recurrent cholecystitis, without and with stones; 3, empyema of the gallbladder, usually with ulcerations; and 4, malignant diseases of the gallbladder.

Inasmuch as the diagnosis must be based on the symptoms in conjunction with the objective findings, it will be best first to sketch the important symptoms before discussing the diagnosis of the different gallbladder lesions.

1. *Acute cholecystitis.*—There are present fullness and distress in the right hypochondrium; anorexia and sometimes slight icterus; no fever or a moderate rise in temperature for a few days.

2. *Recurrent or chronic cholecystitis.*—There exists a repetition of the same symptoms with increased severity and duration or typical attacks of severe colicky pains of comparatively short duration occur, usually in the right hypochondrium, radiating to the back and upward. Stones in the cystic duct are ordinarily accompanied by the symptoms of recurrent cholecystitis. Here, however, the attacks of colicky pain play a more predominant part; jaundice of a mild degree may occur. Stones in the choledochus and common duct present symptoms similar to those in the cystic duct, with the addition of jaundice. The latter is present in varying degree, depending upon the completeness of the obstruction and upon the length of time the stone became incarcerated.

3. *Empyema of the gallbladder* presents an irregular septic temperature; severe pains in the right hypochondrium; rigidity of the right rectus; extreme tenderness on pressure of the right upper abdomen; marked swelling of liver. The blood reveals a leucocytosis and an increase of the polynuclear cells. In addition to the very severe colicky cramps the patient suffers almost continuously and presents the characteristics and appearance of general septicemia.

4. *Malignant disease of the gallbladder.*—Cancer of the gallbladder is present for a considerable time without showing symptoms. The latter result from

*Read before the Medical Society of the Greater City of New York, April 19, 1920.

complications involving other organs, namely the bile ducts, causing icterus, or the pylorus, or duodenum, giving rise to isochochymia.

In making a diagnosis of gallbladder lesions it is of first importance to recognize in a general way the organ affected and then, if possible, to make

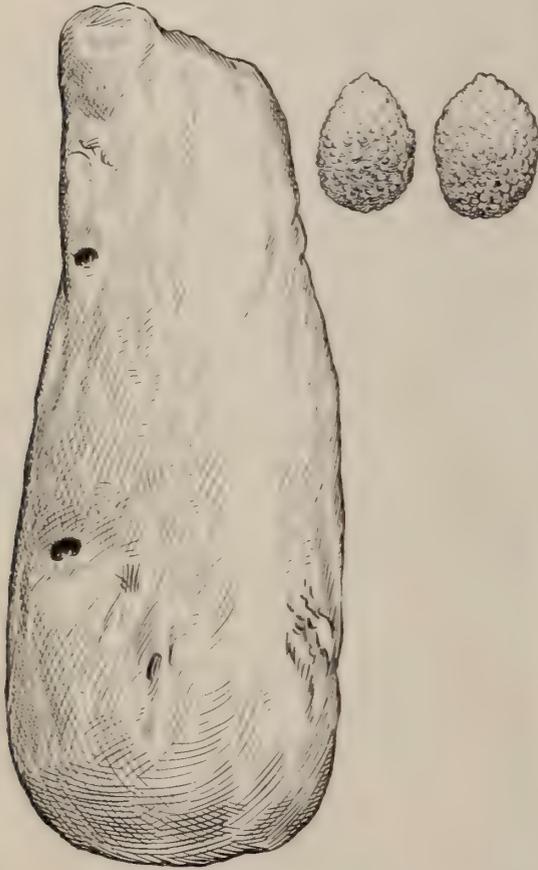

FIG. 1.—Gallbladder of patient C. A., and two stones, natural size.

a more detailed statement with regard to the special disease present. The diagnosis is comparatively easy, when the affections of the gallbladder run a typical course, but extremely difficult when they appear, as they frequently do, in disguised forms. It is principally in these latter conditions that we must avail ourselves of all the more refined methods in order to come to a correct conclusion.

In addition to a consideration of the subjective symptoms and a physical examination, we make use of the x ray apparatus, and employ the duodenal tube and the duodenal bucket and string. The röntgen examination consists of a direct investigation of the gallbladder region, 1, to determine whether visible shadows can be detected; 2, to ascertain the position of the duodenal cap and duodenum after a bismuth or barium test meal, in order to see whether these portions of the intestinal tract occupy their normal positions or are distorted by the interference of the gallbladder lesion; 3, to ascertain if there are any stones in the gallbladder causing a depression of the cap; or adhesions between the former organ and duodenum and pylorus producing a lengthening of the pylorus and duodenum with a dragging away to the right.

Negative x ray findings with regard to the gallbladder do not mean much, for the majority of gallstones do not throw shadows on the screen. Again, the accidental study of a biliary calculus by the x ray, in a patient who does not present any symptoms of gallbladder disease, will simply show that the individual in question is a gallstone carrier.

The direct examination of the bile, obtained from the duodenum, in the fasting condition of the patient, is of great importance for the diagnosis of gallbladder lesions.

While normally the bile, as found in the duodenum when fasting, has a golden yellow appearance and is clear, in pathological conditions of the biliary apparatus it is turbid, greenish yellow or dark brown in color and contains mucus, pus, frequently bacteria and cocci, as well as accumulations of cholesterin and bilirubin calcium crystals. The greater the deviations from the normal, golden yellow and clear, with regard to the turbidity and color, usually the more severe the gallbladder affection.

In cholecystitis, without the presence of stones, turbidity of the bile with mucus and pus are found. In cholecystitis with stones, microscopically, numerous cholesterin and calcium bilirubin crystals are encountered in addition to the mucus and pus.

In complete obstruction of the choledochus and of the common duct there is no bile present, even after prolonged aspiration or duodenal lavage. In common duct obstruction the pancreatic secretion is likewise not found.

The duodenal bucket and string test are useful in the differential diagnosis, especially with regard to the presence or absence of a peptic ulcer. Clear bile obtained by the duodenal tube (or found as such in the bucket) and a distinct blood stain on the string speak for peptic ulcer and a normal gallbladder. Turbid bile with no stain on the string indicates the presence of a gallbladder affection. Turbid bile and a marked blood stain on the string rather point to a double affection, namely peptic ulcer and cholecystitis.

As examples of the aid these newer methods furnish in making a correct diagnosis, I shall describe the following three cases, which I have recently observed:

CASE I.—B. 111-22-20. In October, 1916, the patient had an irregular heart action with shortness of breath when walking for the previous three weeks; he had no pain. The next attack occurred during October, 1918. In November, 1918, the patient consulted me on account of distress and heartburn, which occurred one to two hours after meals. He also complained of slight diarrhea. An examination of the stomach on November, 1918, showed: hydrochloric acid +; acidity, 80.

Since October, 1919, the patient had some difficulty in breathing, principally after meals. On March 8, 1920, the patient woke up with a severe pain in the upper abdomen and he vomited for five hours. The pain radiated to the left shoulder and arm. The next day the patient had a similar attack, for which he required a hypodermic injection of morphine. Almost every day thereafter the patient had a repetition of the colic, and the pain radi-

ated* to the back and left shoulder. On March 16, 1920, the patient entered the hospital.

On March 16, 1920, the physical examination showed the chest to be in good condition; the heart sounds were normal, and the heart was not enlarged. Palpation of the abdomen showed an area tender to pressure below the right costal margin. The stomach was not dilated and the liver was not markedly swollen. On March 17, 1920, an examination of the gastric contents an hour after a test breakfast showed: hydrochloric acid +; acidity, 50; no blood. The duodenal bucket showed no signs of ulceration and a permeable pylorus. The duodenal contents obtained on March 20th, in the fasting condition, revealed a dark brown colored fluid of great turbidity, alkalinity, 40; the ferments all present; $A = 7$; $S = 2$; $T = 6$; microscopically numerous small cholesterin crystals and pus corpuscles were found. Blood, hemoglobin, 80 per cent.; red blood cells, 4,800,000; white blood cells, 11,000; polynuclears, 60 per cent.; lymphocytes, 40 per cent.

A diagnosis of severe cholecystitis with probable stones in the gallbladder was made. An x ray examination confirmed this diagnosis. It showed a large shadow. The patient was then operated upon by Dr. J. F. Erdmann on March 25th. The gallbladder was found enlarged, filled with a mucopurulent fluid containing no bile. The cysticus was dilated and contained a stone the size of a half walnut, hermetically closing up this branch of the bile duct. The gallbladder itself was almost as large as a goose egg, distended with fluid and ready to burst.

CASE II.—C. A., aged forty-two years (January 6, 1920). Patient complained for the last six months of pain over the right hypochondrium, which was most severe after midnight. At times vomiting of bile occurred in the morning. Patient did not partake of alcohol and smoked moderately. He did not chew tobacco, slept well, appetite was good, bowels were always regular. The present trouble began eighteen years ago and was characterized by attacks of acute indigestion, pain over epigastrium, nausea and vomiting, unaccompanied by chills or fever. The attacks used to occur about three times a year, irrespective of the food taken. This condition assumed greater proportions for the past year, the attacks coming on more frequently each week and with greater severity. For the last four months the attacks appeared daily, the pain was more intense and lasted longer. The patient scarcely ever had chills or fever; vomiting occurred frequently. The vomitus consisted principally of bilious matter. The pain was getting worse, especially after midnight. For the last three months the patient would wake up during the night with pain. He would get up during the night, go to the cellar and chop wood. This gave him partial relief. The ingestion of milk would frequently allay the pain somewhat, but not when it was intense. The patient had lost over twenty pounds in weight. An x ray examination showed a deformity of the cap, but nothing abnormal otherwise.

When the patient consulted me on January 6, 1920, he was in great pain. The examination showed the following: The stomach was not enlarged;

the liver was swollen; right hypochondrium painful to pressure, with slight muscular rigidity. The duodenal bucket string test revealed a permeable pylorus and no distinct ulceration in the stomach or duodenum. The duodenal tube aspiration in the fasting state furnished a turbid dark green yellow bile; alkalinity, 25; $A = 7$; $S = 0$; $T = 0$. The blood showed 21,000 white blood cells. While in the hospital the patient was seized with a violent attack of pain in the region of the liver and had a rise of temperature (102° F.).

Notwithstanding the x ray findings of duodenal ulcer, a diagnosis of severe cholecystitis with probable stones and empyema of the gallbladder was made. The patient was operated upon by Dr. Willy Meyer. The gallbladder was found to be almost the size of a fist, greatly thickened, filled with a mucopurulent fluid without bile; toward the cystic duct two stones the size of a pigeon egg were lodged (Fig. 1).

CASE III.—March 14, 1920. Mrs. I. E., aged thirty-four years, had always enjoyed good health except that for the last eight years she had been troubled from time to time with rheumatism. Three years ago the patient began to suffer from attacks of severe pain in the upper abdomen, radiating to the back and right shoulder. The attacks would come on first about once a month, later especially during the last six months, every two weeks. The attacks varied in severity and duration. Some of them were relieved by hot applications, others required a hypodermic injection of morphine; some of the at-

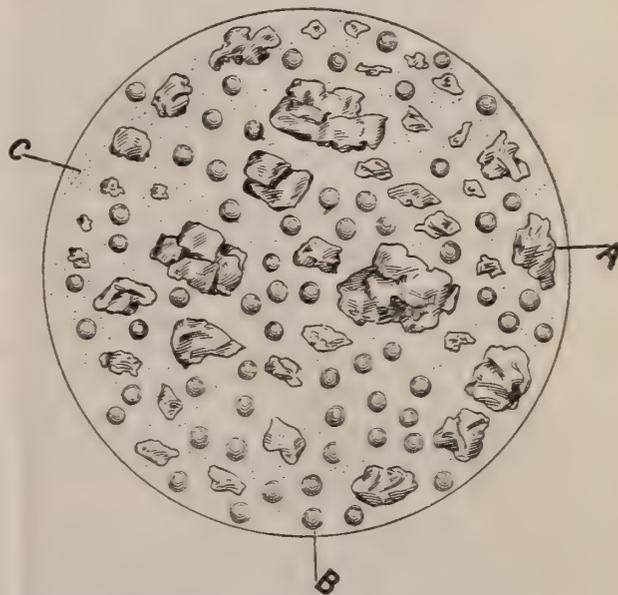

FIG. 2.—Microscopic picture of the duodenal contents (bile) of Mrs. E. A, big cholesterin crystals; B, pus corpuscles; C, mucus.

tacks lasted half an hour, others twenty-four hours. The attacks had no relation to the intake of food; nor were they relieved by food or alkalies. For the last year the patient complained of having attacks of sour stomach, belching, poor appetite, and constipation during the intervals. She frequently had headaches, and suffered from nervousness, dizziness

and spots before her eyes. She had lost about ten pounds in weight.

A few months ago an x ray examination had been made of her gastrointestinal tract. This showed a six to eight hour food retention in the stomach and a deformity of the cap. The diagnosis of the röntgenologist was pyloric obstruction due to duodenal ulcer.

The examinations performed at the hospital showed: The chest organs apparently normal. Abdomen: Stomach markedly dilated, the greater curvature was a hand's width below the navel. Palpation showed a painful area beneath the liver under the right costal margin. The gastric contents revealed: no hydrochloric acid; acidity, 6; no rennet present, no blood. Lavage in the fasting condition of patient furnished water without any traces of food. The duodenal bucket string test showed a permeable pylorus and no signs of ulceration. (Bile at nineteen inches, no blood stains.) The duodenal aspiration in the fasting condition revealed a yellow slightly turbid bile; alkalinity, 25; A=8; S=8; T=4; microscopically many cholesterol crystals; pus corpuscles and mucus. Two blood examinations were made; one on March 18, 1920, showed white blood cells, 6,000; polynuclears, 59 per cent.; lymphocytes, 41 per cent., during the interval. The other on April 5, 1920, during the attack showed

gallbladder was resected. Nothing abnormal was found in the stomach or duodenum.

A microscopic examination of a tiny piece scratched from the surface of the stone showed the same type of cholesterol crystals found in the duodenal contents before the operation. (Figs. 2 and 3.)

In Case I the diagnosis had been made of angina pectoris and auricular fibrillation. The direct examination showed a distinct pathological gallbladder condition and led to a correct diagnosis.

In Case II duodenal ulcer appeared to be the disease in question at first, the deformity of the cap revealed by the x ray likewise pointing to this. The examination of the bile, again, revealed gallbladder disease, while the string test negatived the presence of a duodenal ulcer.

In Case III the symptoms were definite enough to make a diagnosis of gallstone colic. The x ray indicated another disease. The duodenal bucket string test and the aspirated bile, however, led to a correct diagnosis, which found full corroboration at the operation.

The more detailed diagnosis will always have to be made by a combination of all the findings (subjective and objective) present. Thus, turbid bile, fever, extensive leucocytosis, high polynuclear count, considerable tenderness in the right hypochondrium, in conjunction with muscular rigidity on the right side, will point toward empyema or ulceration of the gallbladder nearing perforation. Severe colicky pains in the right hypochondrium, with or without a slight rise of temperature, followed a few hours later by perfect remissions and freedom from pain, will speak for a biliary calculus. Turbid bile will substantiate the diagnosis. The same symptom complex, with jaundice and absence of bile in the duodenum, will indicate a stone in the choledochus or common duct. Intractable jaundice, cachexia, frequent distress, but no sharp colicky pains, preceding the icterus, no bile in the duodenum or presence at times of clear bile, indicate a malignant disease involving the choledochus, or the hepatic ducts.

The treatment of gallbladder diseases can be divided into that of the acute conditions, and that covering chronic states. In both groups medical as well as surgical therapy have their special fields.

TREATMENT.

In acute cholecystitis, with or without stones, the former covering all colics due to biliary calculi, treatment consists of absolute rest, hot applications and the administration of an opiate. A hypodermic injection of morphine with or without atropine, a suppository of opium and belladonna, or the latter with codeine, will be beneficial. Hot drinks of plain water, or camomile tea are useful. Irrigation of the bowel with warm saline and the addition of essence of peppermint (one teaspoonful to a quart), especially when there has been no defecation for a day or two—is likewise beneficial. Usually the acute attack subsides in from one to three days, and there is either a return to the normal or, more frequently, to a kind of a quiescent or latent stage. Acute cholecystitis of great toxicity, giving rise to

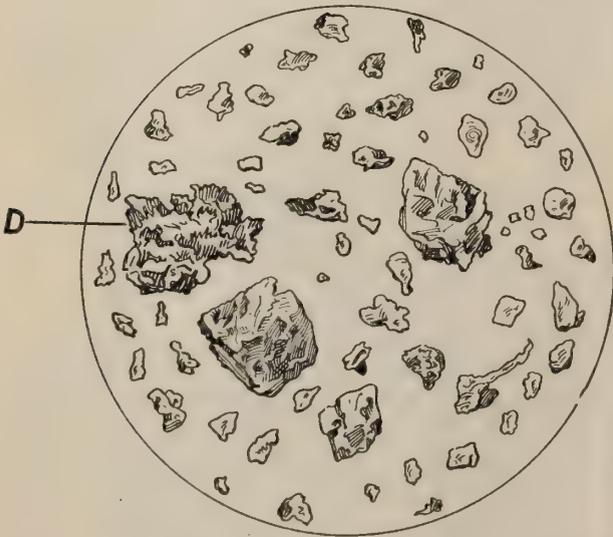

FIG. 3.—Microscopic picture of the scrapings of Mrs. E.'s gallstone, after removal by operation. The same cholesterol crystals are noted as found in the duodenal contents; D, chunk of calcium bilirubin crystals.

white blood cells, 10,000; polynuclears, 66 per cent.; lymphocytes, 34 per cent. A diagnosis of severe cholecystitis, probably due to a biliary calculus, was made and an operation on account of the frequency and severity of the attacks was advised.

Dr. Willy Meyer operated upon the patient on April 7, 1920. The gallbladder was found considerably enlarged (the size of a goose egg), its walls thickened; the mucosa in parts corroded and almost necrotic; toward the cysticus a large stone (the size of a walnut, was embedded; the contents presented a mucous fluid without bile but contained pus. The

emphyema, ulceration or a perforation of the gallbladder, requires immediate surgical intervention. Until the operation is performed applications of ice over the right hypochondrium, the administration of opiates, absolute rest, and very little liquid food form the principal methods of treatment.

The treatment of recurring cholecystitis, with or without stones during the latent stage, has two objects, 1, to reduce stagnation of bile, and 2, to combat the infection. The former is accomplished by drinking large quantities of water. Cures at Carlsbad, Kissingen, Vichy, Saratoga or French Lick Springs combine the advantages of water, mild aperients, and restful surroundings, which are of benefit for establishing a healthy liver function. Frequent and small meals of wholesome food (mixed diet, with plenty of green vegetables and fruits) are likewise of much assistance in increasing the flow of bile. The infection is best combatted by urotropine, salicylic acid, salol, aspirin, and again by flushing the gastrointestinal tract with great quantities of water. I found that glycerin given in teaspoonful doses, three times daily, exerts an antiputrefactive action on the bile. Patients who have been given this medicine furnish a bile that can be kept from one to two days without decomposition, while otherwise, the duodenal secretion after being exposed for a few hours in the air begins to smell badly and in about six hours develops a putrid odor.

This led me to prescribe the following medication which I frequently give in these cases with advantage:

Natr. bicarbon.	3ii
Glycer. pur.	3ii
Aq. dist.	3v
S. ̄ss. t. i. d., one half hour a. c..	

Antiseptic and astringent solutions can likewise be instilled directly into the duodenum, in order to exert a beneficial influence in this locality, which also has an effect on the biliary passages. Ichthylol (one half to one per cent.) or argyrol in the same strength (blood temperature) can be thrown into the beginning of the duodenum in amounts of from ten to twenty c. c. daily or every other day while the patient is in a fasting condition.

When biliary calculi are known to exist and give rise to difficulties through their migrations, olive oil administered in four to five ounce doses once or twice daily, has been believed to have a good influence on the passage of the stones. This can only refer to small calculi; but even then, the effect of the oil is problematical. Its action, however, is never harmful, and it can therefore be employed in appropriate cases.

The indications for surgery in chronic cholecystitis (with or without stones) are as follows:

1. Comparatively severe recurrent attacks of cholecystitis, whether accompanied by fever or not, require surgical aid.

2. Mild attacks of recurrent cholecystitis accompanied by a moderate leucocytosis (especially with an increase of the polynuclear cells) likewise require operation.

3. Chronic jaundice due to obstruction is best handled by operative measures.

4. Gallbladder affections in which there is sufficient reason to suspect a malignant disease should be operated upon as soon as possible.

Contraindications to operative measures are found in severe heart or kidney lesions, diabetes mellitus, general debility and old age. What to do under these circumstances (whether to operate or not) will depend upon the severity of the gallbladder affection and the degree of involvement of other organs. No hard and fast rules can be laid down. A careful consideration of the danger of the operation, and the benefit to be obtained by it, will make a decision possible.

GASTRIC SUPERACIDITY.

Causation and Treatment.

By WILLIAM VAN V. HAYES, M. D.,
New York.

Formerly Professor of Diseases of the Digestive System, New York Polyclinic Hospital.

Gastric superacidity, because of its great prevalence, the distress or pain it causes, and its tendency to progress from mild to severe forms, is a subject worthy of continued study as to its causation and treatment. In this paper the various forms of gastric superacidity will be considered as a group. This includes hyperchlorhydria, in which the gastric juice is too rich in acid; digestive hyperchylia (1), or hypersecretion, in which the gastric secretion is excessive in amount, and usually too rich in hydrochloric acid; also, paroxysmal hyperchylia and chronic hyperchylia (gastrosuccorria of Reichman) (2) in which there is a continuous gastric secretion, even when the stomach does not contain food. These conditions, intermittent or constant, may be functional or the expression of organic disease. The milder forms are likely to progress to the severe ones. Their continuance may culminate in gastritis, the production of gastric or duodenal ulcer, or marked disturbance of intestinal digestion.

FREQUENCY.

Einhorn (3), in a series of 564 cases, found that 286 had an acidity of sixty or over, an hour after the test breakfast. I have just compiled a continuous alphabetical series of 300 cases, in which the test breakfast was used—152 of these showed a total acidity over sixty; eighty-seven over seventy; and thirty-eight over eighty. It may safely be concluded then, that about half the private patients complaining of indigestion, presenting themselves for treatment in New York, have an excess of gastric acidity, if sixty is regarded as the normal limit.

The methods which I usually use in arriving at a diagnosis of gastric superacidity are:

1. The Ewald-Boas test breakfast. One roll, or two slices of bread (about seventy gm.) and one and a half glasses of water (350 c. c.) are given in the morning when the stomach is empty, and expressed, or preferably aspirated, with a bulb specially adapted by me, an hour after the beginning of the meal (Fig. 1). When the aspiration is done, one or two bulbs of air are injected into the stomach to smooth out the rugæ before the gentle suction is employed. After a portion of the contents is aspirated, the funnel is connected, and 200 c. c. of water thoroughly mixed with the remaining contents, and withdrawn. This permits the determination of the total quantity of contents. (Method of Mathieu and Rémond, or more properly Jaworski) (4).

2. Duration test. Two soft boiled eggs, seventy gm. bread with butter, and a glass of water, are

FIG. 1.—Dr. Hayes's aspirating bulb with bevelled glass tip.

given in the morning. Three and a half hours later the stomach, which should be empty, is tested as in the case of the Ewald-Boas breakfast. If for any reason the tube is not used at this time, splashing or gurgling are noted, and two gm. sodium bicarbonate in a half glass of water is given. A notable increase in gastric tympany points to high acidity.

3. The introduction of the tube into the fasting stomach, to ascertain if there is continuous secretion of food retention. The undiluted and diluted contents, when present, are obtained and the determinations made as before. Thus the acidity is determined in the early stage of digestion—again at a time when after stronger stimulation the digestion should be completed; and with the fasting stomach—the three periods of special importance for diagnosis. Incidentally, these tests give valuable information as to the motor function.

ETIOLOGY.

The gastric secretion is affected through the nerves by mental states, nervous diseases, and by reflexes from points of irritation, especially if located in the abdomen, and of these particularly by disturbance in the gastrointestinal tract itself, or the organs directly connected with it. The secretion is also directly influenced by the chemical stimulation of certain food elements and acid acting on the pyloric mucous membrane, through the formation of a hormone (5), "which acts as a chemical messenger to all parts of the stomach, being absorbed into the blood and thence exciting the activity of the various

secreting cells in the gastric glands." The amount and quality of the gastric juice is also affected by the motor function of the stomach. For example: Food held back in the stomach, owing to spasm or obstruction, may cause an abnormal increase in secretion. The endocrine balance and other factors also have a bearing upon it.

The following, therefore, may be mentioned among the common causes of gastric superacidity:

1. Continued mental strain, vexation and disturbing care, have long been held by leading clinicians to be important etiological factors. This is doubtless true, despite the fact that the immediate effect of these emotions in animals (6) and man is to diminish the secretory and motor activity of the stomach. The overworked student, the worried broker, and the sensitive householder who cannot make ends meet, are ready victims of superacidity. With the present world wide conditions, promoting apprehension and mental distress, it will be strange if there is not a notable increase in the type of disease we are considering.

2. Gastric or duodenal ulcer, cholecystitis, cholelithiasis and chronic appendicitis, appear to cause supersecretion, by disturbing the vagosympathetic balance, inducing pyloric spasm. Troublesome hemorrhoids may act in the same way. When these conditions are painful, there is also a mental element in aggravating the difficulty.

3. Rogers (7) and his coworkers have shown that the subcutaneous administration of adrenal extracts, particularly the adrenal nucleoproteids, diminishes the secretion of the gastric juice, presumably by stimulating the sympathetic, or inhibiting nerves, and that extracts of the pituitary gland have a similar action but less intense; whereas certain thyroid, parathyroid, thymus, spleen, liver and pancreas extracts increase the gastric secretion, apparently through the vagi, or activating nerves. Rehfuss (8) reports two cases of total achylia in which the administration of parathyroid was partly responsible for a definite increase in secretion. We may, therefore, infer, that any condition in the body disturbing the balance of these important internal secretions will markedly influence the gastric secretion.

4. Unsuitable food and drink; excess of nitrogenous food; thermal, mechanical, or chemical irritants, as very hot and very cold drinks, coarse foods which are not or cannot be properly masticated; alcoholic beverages, strong tea and coffee; highly seasoned foods, and excess of sugar may induce superacidity. It is said that "in the United States the consumption of sugar per capita a year has gradually increased from eighteen to over eighty pounds in the past fifty years." May this not be a potent factor in causing such widespread superacidity?

5. Partial obstruction of the passage of food through any portion of the gastroenteric tract, with the associated reflex irritation and toxemia, is probably responsible for a large group of overacid conditions. There may be adhesions or bands between gallbladder and pylorus, duodenum or colon; dense bands at the duodenojejunal junction, or Lane kinks in the ileum; or bands compressing the colon or dragging it out of position. Ptosis of the stomach

or transverse colon, or a too free movement of the cecum, permitting sagging and torsion, may bring about the same result.

Lockwood (9) states: "As a clinical fact, whenever food exit is delayed, hyperacidity appears, and the more careful is our examination of patients with hyperacidity, the larger is the number of gastric atonies and motor errors of insufficiency that are discovered." Any condition resulting in considerable delay in the passage of food through the small intestine, I believe tends to induce gastric superacidity in an undamaged stomach. Associated toxemia is no doubt an important contributory factor. Pelvic diseases in women patients should not be overlooked.

TREATMENT.

Gastric superacidity, if at all prolonged, should be regarded with suspicion, and be given the careful treatment it deserves. The tendency, as previously stated, is for the mild conditions to develop into the more severe forms, and a neglected hyperchlorhydria may in time bring on a gastric or duodenal ulcer. It is important to differentiate between the functional cases and those due to organic disease, in planning the mode of treatment, and at times it is extremely difficult to do this; for example, with obscure adhesions, or a latent chronic appendicitis. Fenwick (10) believes that continuous secretion invariably indicates organic trouble (gastric or duodenal ulcer, gallstones or chronic appendicitis). Whether or not this is true, there can be no doubt that with cases of this type, painstaking and persistent search should be made for structural disease. Usually, if all the means at our disposal including the x ray are employed, the diagnosis can be made, and the treatment planned accordingly. As in other branches of medicine, it is important to correct, if possible, the cause of the disturbance. If there is a serious organic difficulty, gallstones, ulcer too severe or deep-seated for medical cure, pyloric carcinoma (an occasional cause of superacidity), bad displacement, or other mechanical conditions not controlled by suitable support of the abdomen, or other remedial measures, surgery is clearly indicated. For the borderline cases, marked hyperchylia, intermittent or chronic, including continuous secretion, medical treatment should be given a fair trial. For the milder cases, the treatment, of course, should be medical.

It must be made clear to the patient at the outset that these conditions are slow in developing, and that it will take persistence and honest cooperation on his part to effect a cure. The essentials in bringing about and holding improvement, are the maintenance of a right state of mind—calm, cheerful, and hopeful; the taking of a correct diet, at the right times and in the right way, and living in a physiological manner in the matter of suitable exercise, sleep, bathing, and dress. It is a matter of common experience that these patients are often relieved by a change of scene and occupation, only to have their symptoms recur on resuming their work, with its attendant cares. At times they recur with added force because of indiscretions in diet while the patient was away. Therefore, the treat-

ment should first be well started, and the patient intelligent and conscientious in carrying out instructions, if much benefit is to be derived from travel.

DIETETIC MANAGEMENT.

The diet must be prescribed for each patient. A theoretically correct diet is given, and this is then modified according to special indications, the response to treatment and the progress toward normal digestion, particular effort being made to reduce acidity, maintain comfort, prevent flatulence, and keep the urine indican free.

All food should be masticated to a fine pulp. For patients who cannot or will not chew thoroughly the food must, in preparation, be finely subdivided. Even then it must be eaten slowly so as to be well insalivated. It is most important that the teeth be free from caries and abscesses, and be put in the best possible condition. The omission of this may be responsible for failure to improve. While it is essential to give food of the right quality, proteids, carbohydrates, fats, salts, and vitamins, in such amounts as to meet the nutritional needs of the patient, an effort is made to avoid irritants in the diet, whether chemical, mechanical or thermal; consequently, mustard, pepper, horseradish, radishes, vinegar, sour tomatoes, strawberries, meat extractives, strong tea, strong coffee, or concentrated sweets are forbidden or greatly restricted. Vegetables with coarse, firm texture, seeds of grapes and berries, skins of fruit or potato skins, fall in the group of mechanical irritants, and while Pavlov (11) has shown that mechanical stimulation of a healthy dog's stomach does not directly stimulate secretion, there can be no reasonable doubt that at least indirectly coarse foods aggravate the troubles which are being considered. Under thermal irritants are included very hot and very cold drinks, and ices if taken rapidly.

Foods should be chosen which do not remain long in the stomach. Usually three meals are given, at five to six hour intervals; though it is sometimes better to arrange at first for three moderate meals, made up chiefly of milk, cream, whites of eggs, cereals, dried toasted bread and butter, at eight, one and six-thirty, and then give a cup of malted milk, weak cocoa or plain milk at eleven, four and bedtime. I agree with Bassler (12) that if a high proteid diet is employed, it should only be as a temporary expedient, to be gradually diminished to a normal percentage as soon as the comfort of the patient permits it. Beginning with a simple diet, the bill of fare may be gradually advanced to include most of the articles in the following list:

Egg albumen, raw or lightly cooked; milk, plain if slowly sipped, or made into soups with vegetable flavoring; plain junket eaten with cream and a little sugar; weak cocoa, or digestible cocoa, made with milk; malted milk, and similar preparations added to milk.

Fine wheat cereals and rice well done; these may be cooked in water or may be given in milk. Fine hominy, oatmeal, cornmeal, macaroni or spaghetti, very thoroughly cooked, may be used in suitable cases. Bread is best given dried and toasted. The addition of raw whites of eggs to the cereals is fre-

quently advantageous. Sugar should be taken sparingly; salt very moderately.

Cream, good butter (without butyric odor), and a little olive oil are the most suitable fats. Yolks of eggs are rich in fats, but should be used sparingly as they often cause distress. Fats, while somewhat diminishing acidity, tend to prolong digestion, and consequently must be given with some caution. Moreover, there is no advantage in giving fats so freely that they disturb the intestinal digestion, and pass off in large quantities by rectum.

Tender flesh foods; preferably white meat fish, chicken and lamb with extractives diminished by boiling, are generally the best foods of this type. As the patient improves, these may be given roasted or broiled, and to enlarge the bill of fare, beef, freed from fibre, or roast beef or steak. Tender fresh vegetables, such as string beans, peas, celery, spinach, summer squash, tips of asparagus, and sometimes young carrots well stewed, may be given to patients who can and will masticate thoroughly; otherwise, they should be made into purees or cream soups. Potatoes, mashed, baked, or twice baked, are allowed when flatulence is slight. Simple cereal puddings; rice, sago, tapioca, if well cooked, or custard made with milk, whites of eggs and about half the amount of egg yolks usually employed; and vanilla ice cream, made with comparatively little sugar (to be eaten very slowly), are types of suitable desserts.

Stewed fruits (sweet prunes, peaches, Bartlett pears), the pulp of a sweet orange, or sometimes half a grapefruit (if eaten very slowly) may be eaten to finish the meal.

MEDICATION.

Alkalies are surprisingly helpful as a rule in increasing comfort, and render important service in this way and by protecting the mucous membrane from the irritating action of a highly acid gastric juice. Unfortunately, in some cases they seem to heighten the activity of the gastric glands, so that after weeks of alkaline medication the test meal may show distinctly higher figures. Five grains each of bismuth subnitrate, heavy oxide of magnesia and sodium bicarbonate, stirred into a glass of water, may be given two or three hours after meals, or about fifteen minutes before the disagreeable symptoms usually appear, and be repeated if necessary. From one quarter to one half a teaspoonful of a mixture of equal parts of sodium bicarbonate and sodium citrate are employed in the same manner. Magnesia is valuable as an antacid and laxative, but may cause intestinal irritation if used too freely, or for a long time. Precipitated calcium carbonate may be substituted for the magnesia if the bowels are too active. Bismuth subnitrate given in dram doses, in water, an hour before breakfast, is very helpful; possibly in part from a mechanically protective action.

Adrenal nucleoproteid (13) and adrenal extract (14) seem to be of distinct value in some cases; but my experience with these is still too limited to draw definite conclusions. Belladonna, one to five minims of the tincture before meals, often definitely diminishes distress; apparently from its sedative ac-

tion, reducing the tendency to pyloric spasm. Strontium bromide, in five to ten grain doses, is sometimes helpful for a short time. Taka diastase, five grains, given during the first half of each meal, is often highly useful in aiding the action of the saliva, before it is checked by the acid secretion, resulting in better digestion and greatly diminished gas formation. Opium and its derivatives should rarely be employed, and then only in the severe attacks for a very brief period.

If there is associated constipation, the patient is taught to massage his abdomen, and only the blandest laxatives should be prescribed, such as purified petrolatum or liquid petrolatum (heavy), a half to one ounce at bedtime. Agar, finely flaked, plain or medicated with cascara, phenolphthalein or rhubarb, one or two teaspoonfuls, softened in water, after meals. Calcined magnesia, ten to twenty grains, stirred in water, at bedtime; compound licorice water, one or two drams, at bedtime; or fluid extract of cascara, freed from the bitter principle, a half dram at bedtime. Small doses of calomel are occasionally prescribed, or if need be, a dose of castor oil. Enemata or colonic flushing may be advantageous. If, owing to dietetic indiscretion, or unknown cause, there is marked nausea, pain and vomiting, the stomach should be emptied by tube if necessary, the bowels cleansed by enema, and one pint of water containing glucose, a half ounce, and sodium bicarbonate, a half dram, given by rectum, Murphy drip method, two or three times daily; no food by stomach for a day or two; then albumen water; later milk and bland soft diet. A warm compress over the stomach may also be employed with advantage. Lavage is not necessary in the mild cases. With marked hyperchylia (gastrosuccorrea), benefit is derived from washing the stomach with a one per cent. sodium bicarbonate solution, or with plain warm water, followed by a one to two thousandths solution of nitrate of silver (14), or a nitrate of silver spray (method of Einhorn) (15). Effective abdominal support is essential for patients with ptosis. This is given by means of a spring supporter, belt or corset, as is most suitable for the patient.

In conclusion, I may say regarding the entire subject of gastric superacidity that although the methods described are fairly satisfactory, there is need for continued research and experimentation, in order that the treatment may be established on more scientific lines.

PRIMARY SACOMA OF THE STOMACH.*

Report of a Successfully Operated Case.

By SEYMOUR BASCH, M. D.,
New York,

Clinical Professor of Medicine at Fordham University Medical School; Attending Physician to Lebanon Hospital.

The subject of primary sarcoma of the stomach is of far greater clinical importance than is generally assumed. A careful study of the literature shows it to be of more frequent occurrence than individual experience would lead one to infer.

Relatively speaking, gastric sarcoma has more often been the subject of mistaken diagnosis than perhaps any other gastric condition. In many instances the clinical and operative diagnosis has been in doubt until cleared up by the ultimate histological examination. In such cases the presumptive diagnosis has almost invariably been cancer. Gastric sarcoma has, however, been mistaken also for many other intragastric and extragastric conditions, e. g., neoplasms of the spleen, tuberculous abdominal glands, abscess of the liver, suppurative peritonitis, pancreatic growths, benign peptic ulcer with secondary infiltrating tumor, and many other conditions.

The character of this neoplasm varies so widely in the different varieties, from extreme malignancy down to almost certain promise of radical cure, that attention to the possibility of its occurrence, as well as to its early diagnosis, are matters of the utmost importance. In numerous instances the diagnosis has been made so late in the course of the disease that operative interference was tantamount to an antemortem procedure. Where, however, early operation was undertaken, radical cure, or at least freedom from recurrence for a number of years, has frequently been obtained. It has been my fortune to have encountered such an early case, and I present it herewith in the hope of stimulating interest in this comparatively rare disease, and also of evoking an active discussion of the various phases of the subject.

CASE I.—The patient, C. C., aged twenty-two years, dressmaker, was first seen by me on January 1, 1919, in consultation with Dr. Joshua Leiner. The family history, aside from the death of her

father from gastric carcinoma, was negative. The patient herself, though a moderate eater and somewhat constipated, had always been stout and enjoyed excellent health. She dated her present illness back to about one year before, when, following a dietary error, she suffered from what she termed an attack of acute indigestion. A laxative was followed by temporary relief for about three weeks, when she began to experience frequent attacks of sharp cutting pains in the right hypochondrium and anterior lumbar regions. These began several hours after meals and lasted three or four hours each time. They were associated with heartburn and frequent belching of sour or tasteless gases. The distress was so acute that relief was sought through forced vomiting. The amounts vomited, especially of late, exceeded those ingested, although food from previous days was never noted. Meat and other heavy foods increased the pains, while fluids often gave relief. The pains, vomiting and other manifestations, had markedly increased during the past three or four months, during which period, too, there had also been a loss of about twenty-five pounds in weight. There was no history of fever, cough, sweats, hematemesis or melena.

Examination showed a thin, anemic, and rather feeble individual, without, however, any evidence of systemic or central nervous disease. The abdominal wall was thin, soft, and relaxed, and the abdomen therefore readily palpable. In the right hypochondriacal and lumbar regions, somewhat to the right of the usual duodenal area, a hard globular mass, about three inches in diameter, could be easily felt. It was smooth in outline, quite tender to the touch, and freely movable. It was especially well felt when the patient arched her back forward, thus stretching the anterior abdominal wall. Its density and firmness reminded one forcibly of indurated tuberculous abdominal glands.

The stomach was considerably enlarged to percussion, the greater curvature being two or three inches below the umbilicus. There was no visible peristalsis or gastric stiffening, no resistance, no other points of tenderness, or any other palpable masses. The free edge of the liver was felt about two inches below the costal margin. It was, however, normal to the touch. The spleen and left kidney could not be felt, though the right kidney was prolapsed to the second degree. It was not sensitive to the touch and apparently normal.

For the purposes of better observation and treatment, the patient was admitted to Lebanon Hospital on January 3rd. Temperature, pulse, and respiration were normal; the blood pressure averaged 105 systolic and 75 diastolic. Occasionally pains of moderate severity were felt in the right upper quadrant. She was placed upon a soft diet which was for the most part retained, although several times there were attacks of slight or even profuse vomiting, which, however, never was sanguineous, but always contained rather large amounts of mucus. The appetite was good. The Wassermann reaction was negative. Examination of both the urine and feces proved negative. Two string tests were attempted, but proved unsuccessful as the

*Presented before the American Gastroenterological Association, at its twenty-second annual meeting, Atlantic City, N. J., June, 1919.

patient vomited each time. Retention tests were also vomited, but one or two successful ones showed evidences of partial pyloric obstruction, viz., a few ounces of stomach contents, containing some of the barley and meat from the previous evening meal, as well as a large number of sarcinæ. There was no gastrosuccorria. In the fasting state the free hydrochloric acid was ten and the total acidity sixty-four; after the Ewald-Boas test breakfast there was thirty free hydrochloric acid and eighty total acidity. Lactic acid was never present.

Diagnostic considerations.—It was seen that we were dealing with an indurated tumor mass located in the middle area of the right side of the abdomen; this mass was definitely circumscribed, easily palpable, freely movable, and rather tender to the touch. The tumor was causing a partial pyloric obstruction, pronounced abdominal pains, frequent attacks of vomiting and sitophobia, and was associated with a rapid loss in weight and strength. There was no evidence of gastrointestinal hemorrhage.

Two pertinent points of interest presented themselves for discussion, viz., the nature of the tumor and whether it was of intragastric or extragastric origin. Although the patient was examined by a number of careful and experienced observers, no positive conclusion as to the nature of the tumor was reached. Neither the clinical course nor the objective findings offered sufficiently acceptable criteria for an indisputable diagnosis. The history of the case and the presence of an indurated tumor were strongly indicative of a malignant growth, and, in an older individual, particularly with a longer history of gastric distress, the recent and rapidly progressive downward course, such a diagnosis would have been justified. But the age of the patient, the absence of free and of occult blood, the presence of sarcinæ and of a high degree of hydrochloric acid, were factors that spoke strongly against malignant disease, and favored rather the existence of a benign process. It was felt that we were dealing here most probably with a pyloric ulcer associated with pronounced inflammatory changes. Sarcoma was not even thought of. The tumor itself was freely movable; its situation was low for the pylorus, and the obstruction was only a partial and not a constant one. These facts led the greater number of observers therefore to favor the diagnosis of an extragastric lesion with inflammatory changes, resulting adhesions and partial obstruction to the pyloric outlet. Among the other diagnoses suggested were omental tumor, inflamed adherent gallbladder, tuberculous peritoneal glands, indurated inflammatory cyst, and even chronic appendicitis, situated unusually high. Discussion of the pros and cons for these various opinions is unnecessary.

The röntgenological examination pointed decidedly to an intragastric lesion. The report stated that the stomach was enormously enlarged, markedly poséd and atonic, with extremely sluggish peristalsis and a large residue after six and even after twenty-four hours. The duodenum was difficult to visualize, but the first portion and also the pyloric end of the stomach appeared decidedly pathological.

The röntgenological diagnosis was "gastrextasy with marked pyloric obstruction, evidently due to an organic lesion involving the pyloric end of the stomach and the first portion of the duodenum."

In view of all the facts mentioned above the case was regarded unquestionably as a surgical one. Operative interference was advised and consented to. The operation was performed by Dr. Henry Roth on January 12th, ten days after the patient's admission to the hospital. A median line upper abdominal incision was made. The stomach was found to be very large and dilated and freely movable. The duodenum, too, was freely movable, but apparently normal. In the pyloric portion of the stomach there was seen and felt a large indurated mass, occupying the greater portion of the antrum and extending down close to the pyloric ring. It was situated intramurally, the serous coat being intact. The tumor surface and outline were smooth, and while the mass strongly suggested an inflammatory infiltration, such as one so often finds associated with chronic ulcerative obstruction, Dr. Roth was decidedly of the opinion that it had the induration of a malignant process. Because of this fact, and also because of the sharply circumscribed area and free mobility of the tumor mass, a complete resection was decided upon. Thereupon, a typical Mayo cautery resection, which included the postpyloric portion of the duodenum and the stomach antrum just proximal to the tumor margin, was carried out. This procedure was followed by a typical posterior gastroenterostomy, done without the use of clamps. Careful exploration of the entire abdomen failed to show the presence of any other growth. The wound was closed in the usual manner, leaving a rubber tissue drain in the duodenal stump.

The postoperative course during the first two weeks was marked by fever ranging from 102° to 104° F., and a disturbed mental state (psychosis) manifesting itself through extreme loquaciousness, irritability, distrustfulness of attending nurses and doctors, and a fixed stare with failure to reply to direct inquiries. On the thirteenth day after operation there was a sudden profuse discharge of a purulent secretion from the wound, followed by a rapid drop in the temperature, and an improvement in the mental state¹. Thereafter recovery was progressive, and the patient was discharged from the hospital on the twentieth postoperative day. She has steadily improved, and now, five months after her operation, feels well and has gained over thirty pounds. In April, 1920, fifteen months after her operation, the patient was feeling very well and had gained fifty pounds in weight.

The gross appearance of the tumor has already been described. It was a rounded mass, three by five cm. in diameter, having a density exceeding somewhat that of a uterine fibroid. The sarcomatous portion was adjacent to the pylorus, while the rest of the mass was made up of dense inflammatory tissues.

The specimen was microscopically examined, and reported upon as follows by the hospital pathologist, Dr. E. P. Bernstein: The mucous membrane di-

¹ The rubber tissue drain had been removed rather early after the operation and this may have accounted for the retained exudate with the associated fever and the mental condition.

rectly over the main tumor mass is comparatively normal, showing only an occasional area of new growth cells between its ducts. The submucosa, which is the apparent origin of the growth, is almost completely replaced by tumor cells—either in masses or loosely distributed between strands of connective tissue. The cells are roughly polygonal in shape with a fairly large, well staining nucleus and surrounded by an abundant zone of clear cytoplasm. Some cells show active mitotic figures. The tumor cells bear no relationship to the blood vessels present. The muscularis is but sparsely invaded by tumor cells which are seen in the innermost portion of the circular layer, but not at all in the longitudinal layer. The serosa is normal. The microscopic picture presented is that of a malignant tumor (large round celled sarcoma) which has not progressed enough to invade more than the submucosa.

In this case as in so many others, practically all reported sarcomata of the stomach, the ultimate diagnosis was a surprise. Despite an increasing and ably discussed literature on the subject, this condition is still regarded as one of extreme rarity, so rare, indeed, that it is scarcely ever thought of when one is confronted with a possible case. Writer after writer has, however, emphasized the fact that sarcoma of the stomach is a much more frequently occurring affection than is generally assumed, and has urged that more histological examinations be made of hastily assumed carcinomata.

In view of this fact, and also of the circumstances mentioned in the opening remarks of this presentation, it is felt that a brief discussion of the main clinicopathological features will be of interest. Those desirous of obtaining further details of the subject will find them interestingly discussed in the writings of Schlesinger (3), Kundrat (4), Fenwick (5), Manges (6), Flebbe (7), Frazier (8), Warner (9), and others.

Sarcoma may be either a primary or a secondary growth of the stomach. Excepting in the case of the lymphosarcomata, the primary form is of more frequent occurrence.

FREQUENCY.

From reports of cases it is generally assumed that sarcomata of the stomach constitute from five per cent. to eight per cent. of primary malignant gastric neoplasms, and about twenty-five hundredths per cent. of sarcomata in general. [Mikulicz and Kausch (1) and (2).] These and all other statistical figures regarding this type of growth are relative only, since many cases of assumed cancer, or, on the other hand (as in the case now reported), of assumed chronic inflammatory infiltration, associated with chronic gastric ulcer, have, upon subsequent histological examination, proved to be sarcomata. Thus, Perry and Shaw (11), in going over the Guy's Hospital series, found that four out of fifty previously reported carcinomata were really round celled sarcomata.

FORM AND SIZE.

This growth may occur as small or large, nodular or diffuse, hard flat tumor masses within the wall of the stomach, or as polypoidshaped projections from the stomach wall either into its lumen or into the greater or lesser peritoneal cavity. The size

varies from a minute nodule to an enormous mass that may, as in Baldy's case (12), weigh fifteen pounds, and almost fill the entire abdominal cavity.

TISSUE ORIGIN AND TYPES.

Sarcomata being a nonepithelial type of growth, never originate from mucous membrane. They may, however, develop from connective tissue, smooth muscle fibre, lymphoid nodule, or from the endothelial cells of the lymph spaces of the stomach. According to their tissue origin they form respectively true fibrosarcomata, leiomyosarcomata (malignant leiomyoblastomata), lymphosarcomata (malignant lymphoblastomata, Hodgkin's disease) and endotheliomata. According to their cellular structure they are classified as small and large round celled and small and large spindle celled sarcomata.

The age of incidence varies widely. Thus, Findlayson (13) reports a case observed in a child three and a half years of age, while di Giacomina (14) reported one in a man aged ninety-one. Contrary to the accepted view regarding sarcomata in general, the age of greatest incidence appears to be, not that of younger individuals, but that between forty and fifty years (Corner and Fairbanks) (15). The connective tissue and lymphoid varieties occur especially in young individuals, while the smooth muscle type is seen more often after the age of thirty to fifty. While opinions differ, the majority of observers agree that the curvatures, especially the greater curvature, are the most frequent seat of origin.

COMPLICATIONS AND DEGENERATIONS

The complications and degenerations are numerous and are associated with the more advanced stages of the growth. They include ulceration, hemorrhage, deformity of stomach outline, obstructions, torsion, cystic and purulent changes, adhesions to neighboring parts and metastases. Metastases may be entirely absent or may occur in neighboring or distant organs, particularly the skin.

Symptoms.—Frequently there is an entire absence of gastric symptoms throughout the entire course, or at least until the growth is far advanced. This arises from the fact that the mucous membrane is not involved and that usually there are no obstructive changes. In many other cases the predominant manifestations are those due to the complications, or to secondary changes in the growth itself, and these have given rise to greatest errors in diagnosis.

The gastric symptoms vary from the mildest expressions of gastric dyspepsia to the severest manifestations of gastric cancer. No definite diagnostic signs and symptoms can be stated. In almost all instances of sarcoma of the stomach the correct diagnosis has never been made previous to direct exploration. In a few exceptions the diagnosis was ventured through the examination of tumor particles obtained from stomach contents, [Riegel (16), Westphalen (16), or through excision of a metastatic growth in the rectum, Schlesinger (17)], skin, glands, etc. That even this latter procedure may be misleading is emphasized by Leube (18), who instances a case of skin sarcomatosis occurring coincidentally with a true epithelial gas-

tric cancer. Dreyer (19), on the other hand, encountered a case of spindle celled pyloric tumor coincidental with a carcinomatous ulcer at the pylorus. The metastases in this case were carcinomatous. As long ago as 1902, Fenwick (20), in his well known monograph on gastric tumors, cites a number of points, attention to which he states makes possible the diagnosis of round celled sarcoma of the stomach. Despite a careful search of the accumulated literature since that date, I have failed to encounter a single instance in which a correct preoperative diagnosis has been reported, excepting through the examination of a metastatic growth, or an expelled tumor fragment.

In a diseased condition, therefore, such as the one under consideration, the occurrence of which, even in a most typical manner, has almost invariably baffled the diagnostic acumen of so many careful observers, it would be an idle task to venture to lay down definitely drawn lines for exact diagnosis. Until the discovery of a specific reaction the diagnosis will probably remain a matter of doubt. The one condition, after all, from which it is most desirable to differentiate sarcoma, is that of carcinoma of the stomach. The importance of this arises from the fact that sarcoma is, on the whole, a much more slowly growing tumor, and, in the relatively early cases, offers a far better chance for a radical cure. Both affections have many characteristics in common, such as the earmarks and accompaniments of malignancy, the alterations in gastric structure and functions, the occurrence of hemorrhages, metastases, splenic tumor, and febrile states. There are, however, some definite distinguishing features which may serve to guide us in clinical differentiation. Thus, carcinoma arises from the epithelium, and though it may involve the rest of the stomach wall, the mucous membrane is always also affected. Sarcoma, on the contrary, as already stated, arises from the nonepithelial tissues, and does not, as a rule, invade the mucous membrane. When it does injure the mucosa, it does so through mechanical force (pressure or erosion). Carcinomata, too, are most frequently located at the orifices and in the body of the stomach; sarcomata, along the curvatures. Hence, carcinomata are more likely to cause early pyloric obstruction. In most instances in sarcoma this is a late complication, and is due not so much to narrowing of the pyloric orifice, as to massive infiltration of the stomach walls. In many instances this massive infiltration causes, not an obstruction, but a gaping of the pylorus. Carcinoma is rapid in its growth and in its general systemic effect; sarcoma, on the contrary, shows quite the reverse characteristics, especially the leiomyosarcomata and the endotheliomata, which are very slow to metastasize. Hence, in carcinoma we more frequently find early local gastric symptoms and signs. Round celled sarcoma is, however, as a rule, a rapidly growing tumor, and, like carcinoma, very prone to metastases. Despite the fact that sarcoma frequently leaves the mucous membrane intact, a number of observers report diminished or absent hydrochloric acid, and even the presence of lactic acid and Boas-Oppler bacilli. Thus, Schlesinger

(17), in three cases, found free hydrochloric acid absent and lactic acid abundantly present; Mathieu found hydrochloric acid absent in eleven out of seventeen cases. Indeed, Harlow Brooks (21) reports that he found both lactic and hydrochloric acid present in his cases, and instanced this simultaneous presence of both kinds of acids as one of the signs that "should lead at least to the serious consideration of the possibility of gastric sarcoma."

Sarcomata being generally less malignant than carcinomata, we find that their average duration is longer than that of carcinomata. Two or three years' duration after the onset of symptoms is not rare.

Occult blood and hemorrhages are relatively less frequent in sarcoma than in carcinoma. Still, attention has been drawn by Manges (6) to a group of sarcomata in which hematemesis is the leading symptom. These, for the most part, were advanced cases. Splenic tumor and fever are more frequently encountered in sarcoma than in carcinoma.

Finally, the spindle celled sarcoma may progress to even quite an advanced stage without giving rise to any gastric symptoms. This applies more especially to pediculated subperitoneal cases that project beyond the body of the stomach, invading the greater or lesser peritoneal cavities.

PROGNOSIS.

The average duration of untreated round celled types is reported to be about fifteen months; that of the spindle celled twenty-four to thirty-two months, and that of the myosarcomata three and a half years. The lymphosarcomata have the greatest tendency to metastasize, and the endotheliomata the least. Naturally, the earlier the removal, the less danger is there of recurrence. Even the most prolific varieties, the lymphosarcomata and fibrosarcomata, give a better prognosis as regards recurrence after removal than do carcinomata.

TREATMENT.

This, of course, in cases not too far advanced, or even in those where the diagnosis is in doubt, or mechanical relief is indicated, should only be surgical. In inoperable cases a course of Coley's serum might be tried. In cases of lymphosarcoma, especially in the inflammatory or Hodgkin's type, arsenic therapy is decidedly indicated.

INFECTIONS OF THE GASTROINTESTINAL TRACT AND THEIR RELATION TO ARTERIOSCLEROSIS.*

BY N. PHILIP NORMAN, M. D.,
New York.

Late Major, Medical Corps, U. S. Army.

Arteriosclerosis, because of its frequency, its consequences and tendencies to cause complications, may justly be called the most important degeneration incident to physical ageing. If recognized early, it is comparatively easy to impress a patient with the possibilities of the situation without unduly frightening him and to institute a course of treatment which will materially benefit the condition as well as inhibit the insidious process in its development.

In this essay I shall present my own ideas of arteriosclerosis as well as my classification of the various types and phases of this disease. For the moment we will review the theories now current so that a contrast of ideas may be more apparent and that the reader may judge impartially of the conclusions reached by observers of this disease.

ETIOLOGY.

In Germany, Thoma's histomechanical theory finds favor, this view being founded upon the atonic muscular conception. His critics state that most cases of endarteritis or arterial degeneration due to faulty or deficient nutrition occur before the loss of muscle tone, as would be evidenced by vascular dilatation. In France and America the autointoxication theory of Metchnikoff is generally accepted. The circulating toxins are said to irritate or inflame the endothelial structures. Opponents of this theory cite that feeding animals upon sterile food soon produces death: that vegetarians suffer from arteriosclerosis and that the degree of arterial degeneration bears no proportional relation to the amount of meat ingested.

The endocrine enthusiasts believe that the burden of the mischief making rightfully belongs to a hyperadrenalism, the physiological excess of adrenal secretion producing a vasoconstrictor effect. Prohibitionists have not neglected the opportunity and insist that alcoholic beverages are the chief causes. The antibacco fanatic is equally as insistent as the prohibitionist that the weed deserves the honor. Other cranks include coffee, tea, and in fact everything that is likely to stimulate our senses pleasantly.

Weil has recently suggested a new theory; that is,

that there is a retention of the lime constituents due to some fault of kidney elimination. He conceives this to be a metabolic perversion akin to gouty diathesis. L. F. Bishop has advanced a very practical theory of arteriosclerosis. He calls the symptom complex, cardiovascular renal disease. He believes that the disease is primarily due to a disturbance of metabolism that has extended over a long period of time before manifesting itself. The metabolic perversion is traceable to bacterial invasion, chemical poisoning, food poisoning, psychic traumas or a combination of these factors. This metabolic disturbance results in a sensitization of the body cells to particular proteins ordinarily found in foods. The three kinds of food found most irritating to the sensitized cells are meat, fish and eggs. This conception is perhaps the broadest of all the theories advanced. It is purely clinical and the results obtained from therapy based upon this theory seem to establish, clinically at least, the logic of the deductions.

However, it seems best to consider arteriosclerosis as part of a general involutinal process occurring during the life cycle of the biological unit. It represents a normal evolutionary consequence, because of the structural complexity of the cellular arrangement not allowing of proper nutrition or adequate removal of waste products from the body cells.

Weissmann and others have shown that protoplasm is potentially immortal. Observing infusoria under a favorable environment which he had prepared for them, he noticed that they lived for generations without showing any tendency to degeneration or death. He proved that infusoria never died except as a result of an accident, improper or insufficient food, the improper removal of waste products or by the radical alteration of other vital environmental circumstances. From these deductions on infusorial life scientists began to inquire why the cells should lose their incapacity for potential immortality when aggregated into the making of a multicellular unit. The fact that infusoria degenerate or die when placed in unfavorable surroundings supported the idea that the multicellular organisms owed their degeneration and death to the development of unfavorable conditions within and without themselves rather than to an inherent propensity to die.

The human organism, like the infusoria, began life with the formation of a one cell organism which divided into two cells after being stimulated by the male sperm. Successive division into two, four, eight, sixteen, thirty-two, sixty-four, etc., occurred. Unlike the infusoria, each cell did not spread in all directions and take up an isolated, individual existence, but clustered together to form a larger and larger cell mass. Soon some of the cells assumed different shapes and clustered more compactly at different points to form the various specialized body structures; muscles, nerves, blood vessels, bones, and other structures, although they all originally sprung from a common source. However, regardless of the specialized functional characteristics which they may develop, they all retain the most primitive of cell functions, growth, nutri-

*Read before the Sixth District Branch of the Medical Society of the State of New York, October 7, 1919.

tion, and reproduction. They all require food for their growth and for their reproduction, and all excrete waste products, the chemical ash, so to speak, of their growth, their nutrition, their productive and vital activities. Since the cells have clustered to form specialized organs with special functions, the problem of adequate nutrition and proper waste removal for each cell of these units became more complex than when each individual cell established an isolated existence after the fashion of the infusorial cells.

The problem of getting rid of waste products and of getting the proper amount of nutrition to each component cell of a multitudinous aggregate, such as a fish, or a cow, or a human, was facilitated by an evolutionary urge which established channels through which nourishment could be distributed to isolated cells and through which channels these waste products could be removed. These tubular structures are the gastrointestinal tract, the blood vessels, the lacteals, the lymphatics, the bronchial tubes, the kidneys, and the skin glands. These channels either supply nourishment or remove waste products or do both. As long as the food supply is properly balanced and the waste removal adequate, good health should prevail, assuming that each component cell is treated alike in a multicellular organism. However, in the multicellular organism, no matter how well the unit is supplied with channels for transporting nutrition and for removing waste products, there are numbers of cells that cannot be reached directly by these channels. For this reason, there is a constant amount of cellular death of isolated cells which is taking place within our body and which is being replaced by the proliferation of adjacent cells more fortunate than its neighbor, as regards nutrition and waste removal, to take the place of the dead cells.

In addition to these defects within the cellular arrangement, our chemical laboratory, the gastrointestinal tract, which prepares the nutrition for the body, as well as eliminating a very great proportion of the waste products of the body, has been imposed upon with a dietary, the cumulative product of the culinary fiendishness of generations of crabbed cooks and irrational chefs, as well as the gourmandizing demands of gastronomic perverts, for which it was never intended to deal.

Modern dietary fuel is so rankly well cooked, so rottenly pleasant to the taste, so poisonously laden with highly putrescent protein, and so viciously full of harmful bacterial and noxious parasites, that it simply blocks the sewerage, if you please, and there results a baneful organic reflex—disease. When this occurs intestinal stasis is brought about and the chemical balance in the colon is lost because of the predominance of bacterial activity that produce putrefactive and butyric acid products. These predominate because the food residue of the average person is so rich in proteids, and is so excessive in quantity, that a fertile and inexhaustible amount of pabulum is furnished for the growth of the harmful bacteria. Because of a lack of starch or sugar residue the helpful fermentative bacteria are starved, decrease in num-

bers and, finally, are not capable of arresting the growth of the harmful bacteria as well as neutralizing the harmful products which they elaborate during their functional cycle. When this occurs, the intestinal functions become impaired, and as a result the food molecules are inadequately or improperly broken up and are carried to the cells to be used in a raw state. The cells have to further digest the raw products for their use.

In the digestion of these raw products, chiefly protein derivatives, a sensitization occurs and later an unmistakable anaphylactic reaction is produced. Add to this the sensitization which is produced by the food toxins, the product of putrefaction, which are absorbed directly through the intestinal walls and into the circulation, as well as the migration of bacteria directly into the circulation and indirectly into the circulation through the lymphatics, and it requires but little intelligence to grasp the significant reaction that will occur in the body's effort to rid itself of a menace which is threatening to throttle its very existence.

Therefore, it seems logical to believe that cellular malfunction, cellular degeneration, cellular ageing, and cellular death are caused in a multicellular organism, such as a human being, by the following factors: 1, Improper dietary; 2, focal infection; 3, a chemical unbalance of gastrointestinal function; 4, intestinal stasis; 5, gastrointestinal infection.

The reaction of the cells of the body are as follows: 1, A sensitization to raw, nutritional products; bacterial toxins and the toxins generated in the colon because of a disturbance of the fermentative-putrefactive balance; 2, a resultant improper cellular digestion; 3, cellular anaphylaxis to foreign chemical substances; 4, a formation of waste residue in the cellular substance that is difficult of cellular elimination; 5, an irritation of the waste removal channels; 6, an inflammatory process involving the waste removal and the nutritional bearing channels; 7, a compensatory, protective, constructive degeneration of the waste removal channels and 8, cellular retention of toxic materials, the cumulative effect of which causes death.

These toxins, the product of microbic activity that are flourishing in the intestines, the oral cavity, the gallbladder, the glandular system and other tissues, during a crisis, somatic or psychical, correlate their energies, become kinetic and are rapidly diffused throughout the tissues, their clinical display comprising many clinical pictures in which the circulatory apparatus always bears the brunt of the attack as it is the channel through which these toxins, food poisons and cellular waste products course throughout the body. Therefore, arteriosclerosis is never due to one factor, not even excepting syphilis, but to a combination of factors, the mobilized toxic products of which produce the arteriosclerosis.

Nervous, mental and emotional stress, the end product of the complexities of the fast changing social order, has to be reckoned with. Psychic conflicts and maladjustments and their compensatory compromises are in a great measure absorbed by the phylogenetically oldest level, that is, the physiochemical level, and any one familiar with a neurology

based upon an evolutionary conception cannot fail to understand that psychic stress is capable of upsetting metabolic or endocrine harmonies. In the battle against this array of enemies and in attempting to intrench themselves the cells may be said to undergo a constructive or protective degeneration, thereby attempting to protect and preserve their function.

PATHOLOGY.

The pathology of all arteriosclerotic degenerations is essentially the same, differing one from the other in respect to etiology and the anatomical structures primarily involved. Three types are usually cited, known as the inflammatory type, the mechanical type, and the nutritional type. It is doubtful whether any one of these three types ever occurs alone.

In the inflammatory type the circulating toxins produce a local endothelial irritation and nature responds to this irritation by a protective hyperplasia of endothelial cells. Thus, endothelial patches are formed, a disturbance of the circulation in the vasa vasorum results and from lack of proper nutrition the patches undergo a granular or fatty degeneration. A thin membrane separates the patches from the circulating blood thus hindering the normal bathing of endothelial cells in blood plasma. Further degeneration of the patches forms a nodule filled with cholesterol debris and fatty deposits. The phenomenon is completed by the deposition of lime in this fatty mass, forming a fatty soap, and later by the formation of the insoluble carbonate and phosphate of lime by chemical action of acid radicals on this lime.

Arterial muscle, being a highly specialized tissue, soon breaks down after adequate vascularization is interfered with. Connective tissue hyperplasia is the constructive degeneration planned by nature, because it requires less blood supply and does fairly well substitute the action of arterial muscle. The degeneration may be incomplete or complete, depending upon the age of the process.

The mechanical type begins in the media with a loss of muscle tonicity, then a vascular dilatation occurs with compensatory tortuosity. The constant overstretching of the muscle of the arterial wall saps its tone. An intimal thickening results from a proliferation of the subendothelial layer. Disturbance of vasa vasorum circulation occurs with a resultant additional degeneration of muscle and of proliferated cellular elements. Lime deposits and the fatty masses then undergo the analogous chemical changes described under the inflammatory type.

The nutritional type differs in that proper nutrition is withdrawn and there is a resultant rapid muscular degeneration with the formation of minute atheromatous abscesses and aneurysmal sacs. Connective tissue replaces the muscle and elastic tissue.

On analyzing the preceding remarks concerning the pathology of arteriosclerotic degenerations we are impressed with the fact that there is much in common in all types. It appears that there is first an irritation factor at work, followed by a protective reaction on the part of the specialized tissues apparently to protect the most useful coat of the arterial wall, the muscle and elastic tissue, then a disturbance of vasa vasorum

circulation, followed by a degenerative process which forms connective tissue to replace a wasting muscle and elastic tissue. The connective tissue substitutes for the muscle.

Reasoning that arteriosclerotic changes are normal phases of an involitional process, it would appear that these changes when normal or abnormal are brought about by nature in a conservative attempt to protect the biological unit. Therefore, it appears within reason to consider arteriosclerotic changes compensatory and, therefore, to constitute a constructive degenerative process.

SYMPTOMS.

An attempt will be made to outline only the symptoms that are associated with early arteriosclerotic changes. Late symptoms are so manifestly indicative that diagnosis is practically possible by listening to the complaints alone. Degenerating blood vessels give rise to no early symptoms. Subjective symptoms and sensory disturbances may arouse our suspicion of organic disorder long before objective findings are demonstrable. There may be no relation of disease and symptom.

The earliest sign of arteriosclerosis is an increase in arterial tension. Bishop has called attention to exceptions of this rule, especially found in arteriosclerotics with neurasthenic states. Occasionally, the normal difference of pulse rate when standing and when in a recumbent position is not maintained. One may suspect an organic process if the rate standing is less than six over the pulse rate when reclining. Palpitation after eating, smoking or sudden exertion is common. Inability to lie on the left side without producing palpitation or cardiac discomfort is frequently found. Headache, especially on awakening or after smoking, is a symptom often associated with early sclerosis of the cerebral vessels. Muscular twitchings; muscular cramps nocturnal and after exercise; tremors of the face, tongue and fingers; tinnitus; dizziness; diplopia; blurring of vision; gastric and abdominal distress, as flatulence, meteorism, constipation with alternating diarrhea are significant in a patient of forty or over.

Sensory disturbances, such as flushings, formications, numbness and tingling, head pressures and fainting sensations, are common. Nervous disturbances, such as irritability, intolerance of others, lack of vital interest, depression and phobias often manifest themselves. Insomnia is a distressing symptom at times.

DIAGNOSIS.

A careful study of the individual's symptoms and an attempt to explain their source rationally will justify repeated and thorough observations. Perhaps the earliest physical sign is a hypertrophy of the left ventricle with an accentuation of the second sound and increased blood pressure. Functional tests may demonstrate a blood pressure rise following exercise and later a rapid fall to a point below the initial pressure, evidencing a lack of integrity in myocardial tone and a deficient cardiac reserve. Associated with these physical signs may be albuminuria with or without casts and indicanuria.

Ophthalmoscopic examination of the retina often

demonstrates early vessel change. Increased tortuosity, beading of the vessels, increase in wall opacity, widening of the central light streak, an interruption of the continuity of the veins where they cross arteries and just beyond this point a dilatation, and evidences of punctate hemorrhages are diagnostic.

Personal observations have led me to believe that a dilatation of the skin capillaries along the course and level of the eighth intercostal space, extending usually from a point midway between the midsternal line and the nipple line to about the midaxillary line, usually bilateral, but in early cases more marked on the left side, is practically diagnostic of early sclerotic changes. It is at this point that a ridging of the skin occurs when stooping or sitting in a position cramping the chest, no doubt obstructing free circulatory movement, and results in this dilatation because of a loss of muscle tone in these small vessels. I have repeatedly made this observation in patients who presented no physical signs and complained of but few sensory disturbances but who presented definite sclerotic changes upon their return a year or so later.

A pharmacodynamic test, using nitroglycerin as a test agent, serves to solve the reason for subjective manifestations in many instances. Many patients, with no physical findings, complaining of distressing symptoms, are promptly relieved with this drug.

Because of the meagreness of physical signs in early arterial disease, one must resort to symptomatic treatment, being very watchful to anticipate a premature or abnormal sclerotic degeneration in patients over forty years of age. The important point to be remembered is that arteriosclerosis begins many years before there is any manifestation, either subjective or objective, of this disease. Indeed, many arteriosclerotic patients are treated for several years as patients suffering from indigestion and the dietary in these cases has not been aimed at a correction of the body metabolism but rather at a local effect on the gastric walls.

TREATMENT.

It is to be kept in mind that arteriosclerotic changes are part of a normal involutional process. If the individual survives long enough, he or she is certain to undergo the cellular changes common to the degeneracy of ageing because of the very structural complexities of the organized multicellular unit. Therefore, arteriosclerosis is physiological as long as the tissue age of the cardiocirculatory apparatus is on a level with the age of the rest of the tissues of the body. However, when from the various causes that have been enumerated, the bacterial toxins, the food toxins and the products of uneliminated cellular waste become mobilized and kinetic, producing a compensatory change in the cardiocirculatory apparatus, which is simply an ageing of these nutritional and waste product channels in advance of the rest of the tissues of the body, the resultant disharmony between the age levels of body tissues is expressed by what I am pleased to call physiopathological arteriosclerosis. Therefore, arteriosclerosis is abnormal only when there is an acceleration of the normal mature arteriosclerotic degeneracy of a given individual or

when the sclerotic changes are premature in their manifestations in relation to the age of the individual.

If recognized early we may hope to remove the excitant factors or at least to hinder or inhibit their manufacture and effect. Cures never occur, for they would be abnormal since arteriosclerotic degeneration is essentially a compensatory process due to the structural complexity of the body. We strive to limit the arterial degeneration to the extent of conforming its age level to that of the other tissues of the biological unit. So to speak, we strive for age harmony of tissues. Premature or abnormal ageing of one tissue secondarily excites the same process in a correlated tissue.

Heretofore, the usual therapeutic efforts have been aimed at reducing blood pressure by the nitrites and potassium iodide, by saline purgation and a restriction of proteids. If an infection was superficial enough to be readily obvious and especially if it produced distressing symptoms it was routinely attended to. The principle of this therapy is essentially based upon elimination. From this theory hydrotherapeutic practice originated, and the work of hydrotherapists, until recently, has been the most efficacious in eliminating the toxic products of the causal factors.

However, the old principles of arteriosclerotic therapy are fundamentally incorrect, because they are based upon a very imperfect and incorrect conception of the disease. Elimination, *per se*, is of benefit temporarily. As soon as one neglects this elimination a reaccumulation of toxic products occurs and again the organism anaphylactically reacts and the disease is fully manifested again. And who can question the stress that is imposed upon the organism by these strenuous eliminatory measures?

Without question, the most logical treatment would be first to find the causes, remove or correct them, and then allow the body to detoxicate itself through the natural avenues and through its own efforts. If the causal factors are removed or corrected a metabolic readjustment takes place and there is no need to drug a patient to reduce his pressure, which is a necessary compensatory reaction, but the pressure will adjust itself to the metabolic needs of the organism in a much more exact manner than is possible for the keenest therapist to discern. Therapy based upon this principle is certain to produce results and the management of arteriosclerotic patients is most gratifying to the patient and to the physician. Arteriosclerosis ceases to be the therapeutic bugaboo of the old days when one grasps the significance of its clinical display and understands the mechanism of its formation.

Foci of infection must be sought for diligently. The gastrointestinal tract must be searched for foci of infection from the mouth to the anus. The intestines contain a great amount of lymph tissue and infection of this tissue is particularly likely to occur as soon as the composition of the digestive juices are altered by a faulty metabolism. Recent investigations have proved that bacteria pass through the intestinal mucosa into the mesenteric lymphoid

tissue and are just as much a source of infection as an abscessed tooth or pyogenic tonsil. Routine blood examination to determine the serology, the cytological status, and other conditions is very necessary. Indeed, much information may be gained from the blood count. The stools should be examined repeatedly and cultures made so as to determine the predominant bacterial flora. It is well to relieve temporarily such patients from all nervous, mental or occupational tension if possible.

To begin with, we know that the dietary has been improper and that a great part of the general cellular sensitization has been brought about by the ingestion of an excessive amount of protein food. Because of this improper dietary, intestinal stasis has occurred. Intestinal stasis alters the chemical composition of the digestive secretions, lowering their germicidal activity and predisposing the intestinal tissues to bacterial invasion. Poor hygiene adds to the misery, and the teeth, the tonsils, the nasal passages and sinuses may become the seat of infection. From these foci many germs escape, to be swallowed, passed on to the small intestines and finally reach the colon, where an excess of protein food residue is delayed in its transit, and supplies a fertile pabulum for the growth of pathogenic bacteria. In addition to these bacteria, think of the countless number that are ingested with food and one may suspect, at least, that the intestinal tissues are having a difficult task in repelling the bacterial onslaught. With this in mind, the scheme of treatment becomes apparent and assumes a logical aspect. First, diet; second, colonic hygiene; third, exercise; fourth, personal hygiene; fifth, temporary palliative therapeutics.

Diet.—Exclude rigidly meat, fish and eggs. The proteins necessary for the dietary balance is derived from milk, cheese, breadstuffs and vegetables. They are nonirritating proteids.

Colon hygiene.—My method is to begin with ounce doses of castor oil combined with ten minims of tincture of iodine and two grains of menthol, every other night for three successive nights, then allowing the bowels to rest for forty-eight hours. This prepares the patient for the cleansing irrigations (hygiene), as the castor oil cleans house from above downwards. The irrigations are begun and are given daily until the colon has been thoroughly cleansed. This is determined by the bacteriological examination of the stool and by the character of the stool. In addition to the irrigations nightly doses of compound licorice powder is given to aid the cleansing process. A special apparatus is used which maintains the irrigating solutions at a constant temperature. The solutions used may be a mildly antiseptic solution, or perhaps a solution of argyrol, protargol or ichthyol. After the colon has been thoroughly cleansed of fecal matter and harmful bacteria one is then ready to plant the colon. This is accomplished by first washing the colonic tract with a solution of lactose so as to furnish culture media for the bacteria that are to be injected into the cecum. Then a pint of a lactose solution containing great numbers of Bulgarian bacilli and the Bacilli acidophilus are introduced through the irrigating tube directly into the cecum. The

patient retains the plant as long as possible. These two bacteria are harmless, if given after the colonic tract has been thoroughly cleansed of harmful bacteria. The success of the treatment depends upon thoroughly cleansing the colon of fecal matter and harmful bacteria before planting the Bulgarian and acidophilus. Unless this is done, it is possible to do much harm. This technic may appear to be simple, but it is not. It requires a constant study of the bacteriological conditions present, in order to determine when it is safe to plant. At times, when the microscopical picture is dominated by pathogenic bacteria, an autogenous vaccine will be found a valuable adjunct to the treatment, as it clears up the infection in the intestinal and mesenteric structures.

This treatment is not to be confused with the high enema or the ordinary high irrigations with which every one has had more or less experience. It is not merely a means to introduce bacteria into the colon, but an efficacious measure in treating infections of the gastrointestinal tract. The surgeon irrigates infected areas, to cleanse the tissues of the germ products, the waste tissue products and because he removes many harmful bacteria, thus aiding the tissues in the process of resolution. The same logic is applied to the colon by this treatment.

This treatment I consider the best and most rapid method of detoxication, and in addition to its detoxicating properties, there is established a new chemical balance in the colon. Putrefactive processes are inhibited by the fermentation products, chiefly lactic acid.

Putrefactive products are the result of bacterial decomposition of protein food residue. The character of the food residue has been changed by the diet and favors the growth of such favorable bacteria as the Bulgarian, the acidophilus and the bifidus. Thus the chemical processes have changed from putrefactive to fermentative, and there is no harmful putrefactive products to be absorbed to further sensitize the body cells. Other foci of infection are treated by methods which are quite familiar to you and need no comment.

Exercise.—Exercise, graded increasingly to a physiological limit determined by the physician, is very necessary because it promotes skin function, elimination by the lungs, a better oxygenation of the blood, a better tissue combustion, heart exercise, circulatory exercise and the formation of optimistic mental attitudes. It is to be emphasized that this exercise is not prescribed for the promotion of pugnacious muscular proportions but chiefly as a heart and circulatory exercise. For this reason, it is well to discourage all forms of games in which the match element is well developed, as the patient is likely to overstep his tonnage.

Personal hygiene.—The patient should be instructed as to nasal, tonsillar, dental and sex hygiene as well as bathing. Habits should be modified. No alcohol and moderate smoking unless there is a distinct reaction to tobacco.

Temporary palliative therapeutics.—If there is insomnia small doses of chloral hydrate is efficacious. If there is precordial distress a nitroglycerin pellet symptomatically used is indicated. For headaches

a small dose of acetanilide combined with caffeine and monobromated camphor usually suffices. Flatulence is usually combatted by resorcin, sodium bicarbonate and pepsin. Palpitation may be helped by atropin or very small doses of aconite hydrobromide, or by a cold water bag to the precordia. Head pressure may be relieved by mustard foot baths. Nervousness usually responds to strontium bromide. For constipation use compound licorice powder or castor oil.

There are a few don'ts which are worthy of mention. First, never attempt to reduce blood pressure by drugs or electricity. Second, never prescribe salines. They do nothing but irritate an already diseased intestinal wall and render it less capable of combatting infectious processes. Third, never deprive your patients of proteids, except those contained in meats, fish and eggs.

The treatment and directions that I have outlined for you will suffice. Rid the body of the patient of the products of food poisoning, the products of putrefaction and the products of pathogenic bacterial activity, and by changing the diet, the habits and the hygiene of the patient you will create a new metabolic level which is infinitely more potent than any drug or electrical treatment or eliminative treatment ever devised by man, for the purpose of arresting the development of the most insidious of diseases, arteriosclerosis, which is being increasingly recognized as the most dangerous menace that is confronting civilization today.

DIAGNOSIS OF GASTRIC DISEASES.*

BY M. B. KUNSTLER, M. D.,
New York.

Attending Gastroenterologist, New York Diagnostic Clinics.

In an organ so accessible to all diagnostic measures as the stomach one would imagine the diagnosis of gastric diseases to be comparatively easy. This, however, is not the case, for even after a most careful and complete examination, we are sometimes in a quandary as to the underlying pathological condition. Among the reasons for this the most important, perhaps, are the facts that the anamnesis is so often misleading, and that we are prone at times to place too great reliance on one particular method of examination. The following means are at our disposal in arriving at a diagnosis: 1, the history; 2, physical examination; 3, test meal; 4, string test; 5, x ray examination; 6, stool examination; 7, blood examination. I shall discuss each method separately, endeavoring to point out its particular advantages and disadvantages.

HISTORY.

Although many men have asserted that this is the most important means at our disposal in diagnosing disease, it appears to me to be very uncertain and of little value, at least in gastric disease. We so often find patients complaining of hyperacidity symptoms where a normal or subacid state exists, that after a time we are prone to lose faith in the patient's statements. And again there are numerous extragastric causes that give rise to symptoms

so similar to the intragastric conditions that were we to rely too greatly on the subjective signs we would surely start with an incorrect assumption. I do not wish to give the impression that the history is altogether unimportant, for many useful facts can be elicited from it. In a textbook case of gastric ulcer the history of pain two to four hours after meals relieved by eating, sodium bicarbonate or vomiting, with frequent attacks of pyrosis, is often as accurate in diagnosing the condition as is a complete and thorough examination. However, I have found that it is only rarely one gets so typical a history and so the anamnesis proves of little value in most cases. An ulcer may exist without any of the usual gastric symptoms, the patient complaining of only constipation, loss of weight, or what he calls indigestion, with nausea at times. The most important point in the history, to my mind, is the statement that the patient has a good appetite but is afraid to eat, or that he has completely lost his appetite. The former is the usual case in ulcer, the latter in carcinoma. The time element is another important factor, ulcer cases giving a history of long duration, possibly five or ten years with periods of intermission, whereas carcinoma dates back only a short time and is progressive and constant. This, however, is not nearly so valuable as the previous statement. The fact that the symptoms are aggravated by the taking of acids usually points to a hyperacidity, although this may exist with a normal or subacid condition. Other important factors to be elicited from the history are the statements pointing to disease of other organs, for a mere hint that some uterine or renal disease exists may prove of extreme value in the final cure.

PHYSICAL EXAMINATION.

A careful physical examination is perhaps of as great value as any other one diagnostic method, for by it we learn not only the gastric condition but also the presence or absence of other diseased organs. Referring to the stomach the physical examination should aim to elicit the following: a, points of tenderness; b, masses; c, position; d, size; e, rigidity; f, peristalsis.

a. Tenderness.—Regarding tenderness one must be extremely careful, for nothing is more variable than abdominal tenderness. Tenderness over the abdominal nerve plexuses, particularly the celiac and aortic, may lead one to suspect almost any pathological condition and has often condemned the patient to needless surgical intervention, so we cannot be too painstaking in distinguishing between this type of tenderness and that due to disease of the viscera. Plexus tenderness is always deep, usually bilateral, and exists without rigidity. The principal gastric diseases producing tenderness are, of course, ulcer and carcinoma. In the former there exists, usually, a superficial point of tenderness in the epigastrium about three inches above the umbilicus, which may be elicited by gently tapping the abdomen in this region. Another tender point in ulcer is found just below the left shoulder blade, posteriorly. The tenderness of carcinoma is deeper and is not localized to one point but exists over the whole area involved. In duodenal ulcer the tenderness is usually lower, being situated to the right

*Presented before the New York Diagnostic Society, May 26, 1920.

and just above the umbilicus. This, however, resembles gallbladder tenderness and it becomes difficult at times to distinguish between the two diseases. In ulcer pressure inward and upward is the most sensitive, while in gallbladder disease the most marked tender spot is elicited by pressure upward and to the right in a line from the umbilicus to the tip of the right shoulder. In appendicitis we sometimes find a tender spot in the epigastrium, but pressure over McBurney's point is so sensitive as to foreshadow this.

b. Masses.—A mass in the epigastrium should always arouse our suspicion of carcinoma until proved otherwise. Carcinoma cases rarely come to us so early that a mass cannot be felt. A small nodule only may exist although usually the mass is diffuse, superficial, irregular, and freely movable. The principal enlargements from which carcinoma must be distinguished are liver, splenic masses, and those due to omental or peritoneal diseases. In the two former the outlines of the organs can often be traced by palpation or percussion and it will usually be seen that the epigastric mass is part of one or the other organ. In peritoneal or omental diseases, such as tuberculosis for instance, the growths are far more diffuse and less freely movable than is that of gastric carcinoma and we get the other signs of general peritonitis, among which are free fluid in the abdomen, temperature, and pulse reaction.

The mass in benign gastric conditions, such as stenosis or chronic ulcer, is very much smaller and more localized than that of carcinoma and besides does not give the general signs of cancer. Syphilis of the stomach gives no mass unless it exists in the form of a gumma, and this is so extremely rare that a differential diagnosis from cancer presents many difficulties. Even when other marked signs of lues are present I hesitate to call a gastric mass a gumma until cancer has absolutely been ruled out. The mass of pancreatic cyst is situated in the epigastric region but is usually regular and nonmobile. Here, too, cachexia is lacking.

c. Position.—Our means for determining the stomach position in a physical examination are percussion and the eliciting of the splash. In the former we may inflate the stomach or not, and then outline the gastric tympany which gives some idea as to position. The splash of the gastric contents is heard when we tap the abdomen in the epigastric region around the umbilicus. Both of these methods lack the accuracy of the x ray in showing the position but for general purposes may prove sufficient.

d. Size.—This is shown by the methods used in determining position and the same may be said as to the lack of accuracy.

e. Rigidity.—The importance of rigidity in gastric diagnosis lies in the fact that in a perforated ulcer this is perhaps the most important sign. In these cases, if seen early, there is marked and localized epigastric rigidity. Later the entire abdomen becomes rigid, indicating a general peritonitis. In gallbladder disease there usually exists a moderate degree of rigidity in the right, upper quadrant, but nothing like that in a perforated ulcer.

f. Peristalsis.—Visible gastric peristalsis is present in malignant or benign pyloric obstructions that

have existed for some time, allowing the stomach muscles to adjust themselves to the condition by hypertrophy. It is most marked in the benign stenosis, for they are usually of longer duration and do not involve the stomach wall as do the cancer cases. In thin people we sometimes are able to see intestinal peristalsis through the abdominal wall, but this is much more indefinite and lacks the regularity of the peristalsis in pyloric obstructions.

THE TEST MEAL.

This is of equal or even greater importance than the physical examination, and had I one method only to choose in arriving at a diagnosis I would take the test meal, for by it we get a wealth of information. It is perhaps best first to describe the normal, and then the variations in the test meal. In a healthy individual we find that the stomach tube enters easily to about nineteen or twenty inches. This is important, for in cases of cardiac spasms or esophageal obstruction (cancer, aneurysm, etc.) we find a distinct blocking to the entry of the tube, and in gastropotosis the tube may be inserted to twenty-five inches or more before it encounters the lower border of the stomach. In aspirating, which by the way should always be done in taking a test meal, the return in healthy individuals varies between five and thirty c. c. (after one hour) and is of the consistency of well cooked oatmeal gruel, being rather slimy and more fluid than solid. It comes through the tube easily, is light yellow in color, and odorless. I refer to the Ewald test breakfast, consisting of a slice of white bread and a glass of water, which for practical purposes is sufficient, and I have found that the one hour period usually gives as much data as do the newer fractional methods, with less disturbance to the patient. The acidity of such a normal meal is about thirty or forty free acid and fifty or sixty total acid, and contains some starch granules without much else of importance.

The most common deviations from this are found in duodenal or gastric ulcer, carcinoma, achylia gastrica, and gastrosuccorrea. In ulcer should there be no obstruction at the pylorus the return is usually small in amount, varying between five and fifteen c. c., and is a thin, clear fluid containing very few food particles. This, of course, means that there is a gastric hypermotility, the meal having been rushed through the pylorus. Where obstruction at the pylorus exists in chronic ulcer the return is extremely large (from 150 to 500 c. c.), of a very foul odor, and contains not only all of the test meal taken but also elements of previous meals, such as carrots or spinach, which may have been eaten two or three days before. In both of these cases, either with or without obstruction, there is a very high acidity, the free acid being from forty to eighty and the total acid from eighty to one hundred, and they may each contain traces of blood. With obstruction there also exists varying amounts of lactic acid and sarcinae. I have also found the Boas-Oppler bacilli with benign obstructions, so this does not become a differential point from cancer. The test meal in the latter is also large in amount but differs from almost every other condition in its

color, being of a dark, red brown hue, having the so-called coffee ground appearance, which is due to the presence of blood. It is of very foul odor and almost always shows an absence of free acid with a low total acidity (fifteen to twenty). Lactic acid is marked as is blood, and we usually find *sarcinæ*, Boas Oppler bacilli and undigested meat fibres. At times we may find great numbers of gastric epithelial cells and pieces of the neoplasm rarely.

The meal of achylia gastrica is also individual in appearance and a diagnosis can usually be made by the way it returns through the tube. It is always small in amount indicating a gastric hypermotility, but its main feature lies in the fact that it is glairy and is aspirated with great difficulty. The food particles are usually large and undigested and are covered with mucus. It is perfectly odorless and of normal color, contains very little or no free acid and about thirty total. It shows an absence of lactic acid, *sarcinæ* and Boas Oppler bacilli, such as are found in cancer. The test meals in pernicious or secondary anemias often show an achylia, and in these, due to the low blood state, it becomes important to differentiate from cancer. However, they lack the characteristic color of the meal in carcinoma cases and show no signs of retention.

In gastrosuccorhea the stomach contents are markedly increased, averaging 250 to 300 c. c., of a thin fluid consistency, and contain very few food particles. If colored at all they are slightly green from the presence of bile. In these cases there is the greatest amount of acid, about eighty free and one hundred to one hundred and twenty total. There is usually nothing else of importance found. The presence of bile in the gastric contents means a patent pylorus with a regurgitation from the duodenum, and is often found in atonia gastrica. So, taken all in all, I think that it will easily be seen how important is the test meal.

STRING TEST.

Regardless of all arguments against it I believe the string test is of great value. In a normal case the string shows no blood stain but is covered with bile from about the twenty-three inch mark onward. Ulcers on the lesser curvature usually show a marked blood stain at about twenty-one to twenty-two inches, while those on the walls or the greater curvature may or may not show blood. I believe the stain must be fairly well marked to be diagnostic and do not think that a very small, barely visible stain is trustworthy evidence of an ulcer. In pyloric obstruction the string shows no bile stain and in carcinoma the blood stain is diffuse, covering eight to ten inches of the string. So used with judgment the string test becomes of great importance.

THE X RAY.

A peculiar controversy has arisen between röntgenologists and internists. It seems to me that the latter accept the former's statements, with necessary reservations as disclosed by clinical findings, while the x ray specialist is neither willing to accept nor discuss any findings except his own. This is probably due to the fact that x ray findings are visual and they say: "What we see we know." The fault lies not in the sense, but in the interpretation thereof, and if the röntgenologist would more often state

what was visible without attempting always to diagnose, the internist would, I am sure, be grateful. In gastric work when one sees cases diagnosed röntgenologically as pyloric cancer or perforating ulcer where no such condition is found operatively, we necessarily become a little skeptical of x ray findings. The only true method is to put all of our data into the form of a brief and by careful study to arrive at as nearly a correct diagnosis as possible.

In determining the size and position of the stomach there is no method as accurate as the x ray. It is also definite in marked duodenal ulcer with deformity of the cap, in carcinoma where the stomach wall becomes deformed or eroded, and in pyloric obstructions. However, in small lesser curvature ulcers or erosions, where gastric hypermotility and a seeming defect are the only x ray evidences, we must tread very carefully before accepting such proof, for it may be only a perigastric adhesion or a slight spasm in the gastric wall that causes the defect in outline. Röntgenological retention, unless marked and of long duration, is of little value compared with that found by the test meal, for a six hour retention may be ignored and the other types show only bismuth stasis without giving signs of the fluid retention. Early carcinoma at the pylorus, as shown in the röntgenogram, must never be accepted unless there are some clinical findings to support the x ray for we may get a flattening of the pyloric end of the stomach which resembles cancer without such being the case. To divert from the stomach for a moment, it appears that the gallbladder is often accused, röntgenologically, of enlargement where no such enlargement exists and for this we must always be on the lookout. And so I use the x ray in every case, but with reservation.

STOOL EXAMINATION.

The importance of stool examinations lies in the fact that in a duodenal ulcer blood may be found in the stool where none exists in the gastric contents. The other stool findings show pathological conditions of the intestines, or faulty digestion of certain food elements, all of which may play a part in the diagnosis.

BLOOD EXAMINATION.

This must always be done in a complete examination for any gastric condition. The secondary anemia in carcinoma or the pernicious anemia found in some cases of achylia is of utmost importance. The presence of a positive Wassermann reaction may change the complete picture and, in a few cases, a marked eosinophilia may put us on the track of an intestinal, parasitic disease. In some extragastric conditions, such as appendicitis, where all signs point to the stomach, a leucocytosis is important.

I have purposely omitted mentioning many of the conditions causing gastric changes for the sake of clearness and simplicity and have attempted to present briefly the methods of making a complete gastric examination with the interpretation thereof. To summarize, examine each patient completely, take the findings for what they are worth, and place most reliance on the physical examination and the test meal.

46 WEST EIGHTY-THIRD STREET.

AN OPERATION FOR THE RADICAL CURE OF INGUINAL HERNIA.*

BY GEORGE WOOLSEY, M. D., F. A. C. S.,
New York.

More than twenty years ago I settled upon a technic for operation on inguinal herniæ, which proved so satisfactory that I have continued to use it ever since. This operation was a gradual development, combining features of several then in use, and was not therefore original, except as to this combination. In 1896 I published a clinical lecture (1) on a case in which the patient was operated upon in Bellevue Hospital in 1895 for inguinal hernia and urethrorectal fistula. The method then employed was essentially like the original Halsted operation, with figure of eight sutures of silkworm gut through the edges of the incision in the skin and of the external oblique aponeurosis, the cord lying above them. A year or so later, after trying Bassini's method for a time, I adopted my present method but did not publish it, as others having similar features, such as Andrews's method, had recently appeared. I did not see Andrews's publication until many years later and, until I read it, supposed that his operation was identical with mine.

My method has been demonstrated in numerous clinics to scores of hospital interns, one of whom, now a hospital surgeon, recently asked me why I never published it. This led me to look over the literature to see if anything exactly like it had been published. I have found one publication describing an operation practically identical, which I had not read until a few weeks ago. This article was by E. L. Swift, M. D., assistant surgeon, U. S. Army, and was entitled, *A New Form of Operation for the Cure of Inguinal Hernia*. It was the subject of a special report to the Surgeon General of the U. S. Army (2).

The main features of my method of operation are obliteration of the inguinal canal and the external abdominal ring, and fortifying this part of the abdominal wall by, 1, suture of the entire thickness of the musculoaponeurotic wall, along the upper or inner margin of the incision, to the deep surface of Poupart's ligament; 2, by overlapping the lower flap of the external oblique aponeurosis in front of the upper flap, and, 3, transplanting the cord so it will lie superficially to the aponeurosis. I shall describe in a few words the different steps of the operation and some of the reasons for their use.

The aponeurosis of the external oblique is split in line with its fibres from near the upper margin of the external ring to a point two to three cm. above the position of the internal ring, care being taken to avoid injury to the ilioinguinal nerve. It is generally recognized as most important to ligate and excise the sac so high up as to leave no infundibular depression of the peritoneum at the site of the internal ring, which favors recurrence. This high ligation is accomplished, after free exposure of the neck of the sac, by traction on the sac with or without twisting it, then transfixing and ligating

it high up. When the traction or twisting is relaxed the site of the ligature is flat and presents no outward bulging. Twisting is also useful to reduce the contents, like the omentum, which tends to slip by the finger, introduced into the sac in traction to keep the contents reduced. If the operator prefers he may excise the sac high up and close the opening by a continuous suture. Unless the neck of the sac is sutured instead of ligated, transfixion is essential to prevent the ligature slipping off, as I have learned by experience. In an operation for peritonitis, due to an injury in the neighborhood of a hernia, I first operated on the hernia and then, finding no lesion in it, opened the abdomen and found that the ligature had slipped off the neck of the sac, requiring suture of the opening. I rarely resect the veins of the cord unless they are very markedly varicose. According to Halstead (3), the advocate of this procedure, excision of the veins with transplantation of the cord results in atrophy of the testes in ten per cent. of the cases and, not infrequently, in a small hydrocele. This atrophy usually follows a considerable swelling of the epididymis. However, all extraneous fat and connective tissues are removed from the cord to reduce its size.

In case the muscular portion of the conjoined tendon at the internal ring is very thin and weak, I do not hesitate to incise it outward and upward one to two cm. into thicker, firmer muscle, to make a new internal ring, as in Halsted's original operation. This is seldom necessary, however.

In suturing the internal oblique and transversalis muscles to Poupart's ligament, in Bassini's operation, I found that the sutures in the muscle had a strong tendency to cut through. Hence I included the firm inner flap of the external oblique aponeurosis. This serves to take the cutting strain of the sutures off the muscles, as well as to add to the strength of the abdominal wall along the line of the old canal. When this is done there is nothing left to do with the lower or outer flap of the external oblique aponeurosis except to overlap it in front of the inner or upper flap, which still further strengthens this weak area of the abdominal wall. Andrews has well pointed out that when the conjoined tendon is sutured to Poupart's ligament it leaves the aponeurosis relaxed unless it is overlapped.

The main object and most important result of bringing the cord out at the upper and outer end of the incision is to enable one to obliterate the external ring and to make a firm closure of this potentially weak part of the abdominal wall, by carrying the suturing of the musculoaponeurotic flap to Poupart's ligament and the imbrication of the aponeurosis continuously to the pubic bone. Toward the inner end of this suture line the sheath of the rectus is included in the sutures, and in direct hernias it may be necessary to relax this by a liberating incision, or to turn down a flap from it to allow satisfactory approximation to the inner end of Poupart's ligament. The outermost suture through the conjoined tendon narrows the internal ring, care being taken not to compress the cord too snugly. The cord is brought out forward and then is deflected upward by the overlapping lower flap of the

*Read before the Bellevue Hospital Alumni Society, December 3, 1919.

external oblique aponeurosis, so that it passes somewhat obliquely forward and upward and then becomes superficial. Andrews places the cord between the two imbricated layers of the external oblique aponeurosis because he does not like to lose "the valvular arrangement of the passage of the cord." But the anatomical "oblique direction of the cord can benefit nothing when the posterior wall of the canal and the internal ring have a sufficient resisting power to retain the abdominal contents; when they have not, it can afford no assistance" (3).

Cabot (4), in considering the radical cure of inguinal hernia, says that we should make a new canal running upward and outward, so that the downward pressure of the bowels, coming at right angles to the axis of the canal would tend to force its walls together. In the operation I am describing the upward obliquity serves a similar purpose. When we imbricate the external oblique aponeurosis the part of it not overlapped, lateral to the internal ring, will show some relaxation when the patient coughs or strains, unless we carry the incision of the aponeurosis two or three cm. beyond the ring and gradually taper off the overlapping. This also furnishes more of a flap to deflect the cord upward. One, and often two, sutures are always placed external to the cord through the overlapping aponeurosis. It is important to place the sutures on either side of the cord so as to avoid undue pressure on the veins of the cord. This passageway of the cord must be tested with the finger and, if too snug, must be eased by replacing one of the adjoining sutures. There is no more danger or likelihood of compressing the cord here than at the external ring in other operations; perhaps less danger.

To prevent the possible adhesion of the cutaneous cicatrix to the structures of the cord, and to be sure that they are covered by the entire thickness of the subcutaneous fat, I suture this fatty layer separately with interrupted sutures of plain gut. No. 1 chromic gut is used for the other buried sutures. The inclusion of the external oblique aponeurosis in the suture of the muscles of the conjoined tendon to Poupart's ligament, described above, is common to Andrews's operation and that of the Mayo clinic, as described by Judd (5). Judd speaks of including it to help hold the internal oblique, as I have done. Both of these operations also imbricate the external oblique aponeurosis, but the cord is placed between the layers. Fowler (6) describes an operation with imbrication of the aponeurosis, but with the cord beneath both layers and without including the aponeurosis in the suture of the conjoined tendon. Championniere imbricated the aponeurosis in the reverse direction to that described above, but he left the cord undisturbed. In the operation described by Halsted in 1903 (3), and called by Binnie (7) the Johns Hopkins operation, there is a multiple imbrication of the separate layers, but the vas is left undisturbed.

In the original Halsted operation and in those described by J. O'Connor, Postempski, and others, the cord is placed superficially, but there is no imbrication of the aponeurosis, and the latter is not included in the sutures of the conjoined tendon. In hernia associated with undescended testis, the cord

is not transplanted, but the method of suture and imbrication described above is employed.

In the female the operation is very simple and should give no recurrence. The round ligament is not transplanted and is included in one or more sutures at the inner end of the incision, to fasten it to the pubes and prevent its slipping and losing the support it gives to the uterus. The suturing and imbrication are done as usual, except that there is no opening left, the abdominal wall being completely closed. My experience has been mostly with hernia in adults or adolescents. In young children hernia can be cured by a simple operation.

The operation I have described is peculiarly effective in direct hernia for it enables the weak portion of the abdominal wall, at the base of Hesselbach's triangle, to be firmly closed by the overlapping of firm structures, without leaving an opening for the cord to pass through them, as in most operations. It is also as serviceable in indirect hernia as any operation that I know of. There are a number of good hernia operations. I do not assert that this is by far the best, but that in my hands it has proved at least as good as any. I have operated on hundreds of hernia with most satisfactory results. I cannot give statistics, as most of the operations were done before a follow up system was introduced. I have seen a few, but very few recurrences. The operative mortality is practically nil. If recurrences were frequent the chief objection to the operation would be in reoperation, by one who did not know the type of operation done, and consists in the danger of injuring the cord, lying superficially, by making the incision down to the aponeurosis too freely. It is also possible to compress the cord, so as to result in thrombosis of the spermatic veins, but there is no more danger of this than in Bassini's or any other operation.

117 EAST THIRTY-SIXTH STREET.

Volvulus Appearing as a Late Complication in an Appendectomy.—Gustave Dardel (*Correspondenz-Blatt für Schweizer Aerzte*, December 25, 1919) reports a case in which he performed an appendectomy on an eight year old girl. Nearly a month later the child presented symptoms of ileus, which could not be ascribed to an error of diet. The condition of the child was good at first, but after some hours became bad. Operation seventeen hours after the onset of the symptoms revealed a gangrenous loop of intestine nearly ready to rupture. This loop was excised and the child recovered. The prognosis in volvulus is very grave. The writer states that with the single exception all previously reported cases have proved fatal.

CHOLEDOCHITIS, CHOLECYSTITIS AND CHOLELITHIASIS.*

The Need of Early Diagnosis and Treatment.

By B. B. VINCENT LYON, M. D.,
Philadelphia,

Associate in Medicine, Jefferson Medical School; Chief of Clinic,
Gastro-Intestinal Department, Jefferson Hospital, Philadelphia.

There is probably no six inches of the entire alimentary canal in which states of organic disease are so prone to develop as in the first and second portions of the duodenum; nor is there any zone into which the elements of differential diagnosis enter in a larger and, at times, more perplexing manner. This, the hot bed of digestion, has emptying into it the mixed or mixing secretions from the stomach, the liver, the gallbladder, the pancreas and the secretion from the duodenal mucosa itself.

The physiology of the digestive secretions in normal people from these various sources has become better understood during recent years. The pathological physiology of states of disease in this zone has been the subject of much profitable investigation during a still more recent period. Much light has been thrown upon the subject by means of carefully conducted animal experimentation. The more widespread use of the duodenal tube in the hands of capable students of gastrointestinal disease is contributing greatly to our knowledge by clinical experimentation on human beings, both normal and those suffering from disease. We have learned how to interpret our findings in the duodenum much more clearly and accurately; we can quite easily determine states of duodenitis and can differentiate those that are catarrhal, those that are infected, and those which show unusual exfoliation of dead and dying epithelium; we can feel reasonably sure of separating our more superficial erosive states from those of true ulceration simply because we are gradually training ourselves to make better use of the materials recovered by means of the duodenal tube for more painstaking cytological, bacteriological and chemical studies.

Differential diagnosis has been gradually extended so that we are now fairly sure of the soundness of our investigations into pancreatic states of health or disease, although there remains a very great deal of work to be done in this field. We have made, too, considerable progress in our ability to diagnose accurately many of the states of disease of the biliary system. But, unfortunately, most of our fruitful efforts, as in the cancer problem, have resulted in the elaboration of various methods and various tests that concern themselves in the proving of disease already well established.

Furthermore, our methods of diagnosis have been more largely indirect than direct. We have learned the value of the carefully taken and searching inquiry into the presenting symptoms, we have learned to interpret more clearly the transition of the earlier symptoms into those that in themselves are almost diagnostic, we have extended the scope and the accuracy of our methods of physical examination, and

our eyes and our fingers have gradually been trained to take cognizance of more minute abnormalities than would have been thought possible a generation ago. Much of this has come about through the pioneer efforts of the surgeons, who have taught us by object lessons in living pathological anatomy at the operating table, the correct interpretation of historical syndromes and of data gained by physical examinations.

We have made great progress, too, in the art of diagnosis of various biliary diseases, as we have caught the importance of focal infection and its march from primary to secondary fields of activity. By the more recently accepted methods of examination of blood chemistry we have learned the significance of an increased amount of cholesterol in the blood serum; we have connected some of the clinical links regarding the incidence of pregnancy, tight lacing, and other conditions with gallbladder disease, especially in relation to the formation of gallstones. As a more direct means of diagnosis we have turned to the röntgenologist for the important aid he can now furnish us with his positive and negative shadows of formed calculi or of increased connective tissue formation in the wall of the pathological gallbladder. But direct as is the evidence given by the x ray, it fails us, perhaps, in half of our cases, and even when supplied serves only to prove a pathological state already well established. In other words, the greater part of our diagnosis of gallbladder problems, thus far made practical, supplies us with information pointing to disease so fully developed that we have been handicapped in applying methods of treatment which, to be successful in ultimate cure, have become more and more radical.

The field of treatment by almost common consent has fallen to the surgeon because our accepted method of medical management have woefully failed to bring results other than palliative.

For a little over three years I have taken great interest in developing a more direct means of differential diagnosis of diseases of the biliary system which lends itself admirably not only to the direct detection of organic disease well established, but also gives promise of a better understanding of functional disorders of the liver and gallbladder and the recognition of pathological physiology which may act as part of the precursory states in the development of the later full blown disease.

We have known for some time that it is possible to drain bile from the common duct and from the liver and collect it by means of the duodenal tube for examinations that have been directed largely to the estimation of pancreatic efficiency. (Einhorn, Gross, Crohn). But a great step forward was made when Meltzer suggested to us a means of making the gallbladder contract and discharge its contents. This has opened an entirely new field of clinical diagnosis and investigation and has widened the horizon of our vision for the recognition and correction of the early states of disease of the gallbladder and ducts that may ultimately lead us to the goal of present day medicine, namely, the prevention of another group of diseases which has claimed a heavy toll of suffering and death. I

*Read before the Twenty-Third Annual Meeting of the American Gastroenterological Society, May 3 and 4, 1920.

allude to gallstones and serious late states of infection of the gallbladder, liver and its ducts.

Meltzer (1), in an excellent article giving his rational conception of the physiology of the filling and discharge of bile from the gallbladder, as governed by his law of contrary innervation, appended a little footnote to the effect that he found that solutions of magnesium sulphate, when locally placed in the duodenum, without first passing over the gastric mucosa, would cause a relaxation of the tonus of the duodenal wall and would thereby relax Oddi's sphincter of the common duct and permit the discharge of bile into the duodenum.

Immediately after the publication of Meltzer's paper, in April, 1917, I was able to demonstrate that the use of magnesium sulphate, locally, in solutions of various strengths, in the duodenum of human beings would very promptly deliver bile through the duodenal tube in varying quantities and of varying quality. It would do this when the duodenum was previously bile free, indicating that the magnesium sulphate had relaxed the sphincter action of Oddi's muscle. Further than this it was noticeable that the character of the bile recovered by means of the duodenal tube underwent certain definite changes in color and viscosity, first a light lemon to golden yellow, then a deeper, richer, more syrupy golden yellow, finally changing to a very uniformly light lemon yellow, thinner and less syrupy than either of the first two; and that this sequence occurred in all normal cases.

It was not long, however, before I examined a patient suffering from symptoms strongly suggestive of biliary disease in whom the second sequence of delivery of the deeper golden yellow bile was replaced by the recovery of over five ounces of deep greenish black bile very viscid, almost tarry. What did this mean? Where was this bile coming from?

The natural inference was that it was coming from the gallbladder. But could it be really possible to drain the gallbladder by magnesium sulphate and the duodenal tube and get it out in a bottle? Yet the cytology of this bile microscopically revealed mucopurulent particles rich in pus cells, large masses of deeply bile stained columnar epithelium, inflammatory debris, masses of bile crystals and was simply swarming with bacteria, chiefly cocci. Culturally the latter turned out to be *Streptococcus viridans*. The patient was operated on ten days later and the gallbladder found to contain bile of the same black color and viscosity and *Streptococcus viridans* was isolated from the bile.

This case and several that had preceded it were the starting point in the use of a method which I first described in a paper (2) and published seven months ago after I had made more than a thousand observations of the practicability of a nonsurgical method of biliary drainage. With certain exceptions, to which I shall later call your attention, it is possible to drain the gallbladder wholly or partially of its fluid contents; to drain the bile ducts and to obtain bile freshly secreted from the liver cells. Furthermore, it is possible to segregate these various biles from their numerous sources by collecting them in individual bottles for chemical,

microscopical and bacteriological examinations that give us a direct method of differential diagnosis between various diseases of the biliary system.

In the direct evidence it furnishes us it far surpasses any diagnostic method yet available, and materially assists our correct interpretation of the presenting history, the physical examination, and the information furnished by the röntgen ray and by the laboratory examinations into the state of gastric chemistry and motility, and of the stools, urine and blood chemistry. But most important of all, it furnishes direct diagnostic evidence of the beginnings of biliary stasis, of masked focal infection that precede the more florid states of biliary disease and give rise later to the symptoms, the physical and laboratory findings that are usually so clear cut as to make a tentative diagnosis of gallbladder disease quite tenable and to warrant the dictum, "We will do an exploratory operation and find out what the trouble really is." This is all very well for the doctor, but a little rough on the patient if there is another reliable and direct alternative method available. In other words, we must learn how to find the direct evidence in the early cases exhibiting the chronic but vague dyspeptic symptoms and not leave it to the exploratory operation to decide whether the trouble lies in the upper right or the lower right abdominal quadrant. Even with the stomach, duodenum and gallbladder well exposed the surgical eye and finger often fails to detect the presence of an early cholecystitis, cholechochitis or duodenitis (usually the forerunner of ulcer), because there is no recognizable gross pathological change (quite ignoring the pathological physiology that precedes gross pathology), and the appendix is then removed usually because it presents a sufficiently pathological condition to warrant it, but not infrequently it is quite innocent and is removed simply because the abdomen is open and it doesn't increase the risk of the operation.

What is the result of this? If there is present concomitant disease of both appendix and gallbladder, as Rosenow's work on streptococci leads many to suspect, and if the gallbladder is harboring streptococci, but in a state of masked focal infection, not severe enough to cause diagnostic symptoms with a parallel gross pathological condition, but nevertheless sufficient to produce a pathological biliary physiology and a positive bacteriology to be found by him who looks, the result is this. The surgeon explores, and finds no upper abdominal pathological condition, no enlarged glands, no stones, no adhesions and the gallbladder expels its contents under forcible digital pressure, (but can it do so under its own muscle power?) and because there is no gross pathological condition the surgeon says everything is normal here, leaves a gallbladder harboring streptococci, and proceeds to account for the symptoms by removal of the appendix. The patient gets well, that is to say, he recovers from the operation, his symptoms improve temporarily, aided by his hospital rest and the removal of his appendix, provided it was in a truly pathological condition; but usually between six and twenty-four months later his symptoms recur, progress in frequency and severity, and change in

character until finally the clinical picture of full blown gallbladder or duct disease presents itself and in the judgment of most doctors operative interference again becomes imperative.

This is not to be wondered at, for it doubtless is true that operative interference is the best procedure at the present time in the properly skillful hands. The surgeons have been successful pioneers in the field of gallbladder therapy because the indirect efforts of the internist with his cholagogues and bile disinfectants, his medicated waters, his diets and his prescription to attend expensively famous foreign spas have been inadequate and uncertain, whereas the direct attack by the aseptic scalpel is productive of prompter results whether good, bad, or indifferent. As Dr. John B. Deaver (3), so apt always in his quotations and epigrams, says in a recent paper, "If thy right hand offend, cut it off." But let us pause a moment and consider. Of course it is easy for the skillful surgeon to cut it off, but it is quite another matter to put it on again if the first experiment doesn't work. It is one thing to remove with impunity the appendix which possesses no (or an unknown) function, (although many an innocent one has been removed in the past, as have healthy tonsils and teeth during their respective crazes), and quite another thing to remove ruthlessly and routinely every gallbladder because some harbor streptococci in their lymphatic tissue and in their walls. As I have said it is all very well with the patient if it works. But suppose, and we know that this often happens, for the surgeons tell us, suppose the common duct remains infected after surgical drainage is completed and later becomes obstructed, what happens then when the distensible reservoir for liver bile has been removed? The safety valve has blown off. The common duct dilates and vicariously tries to assume the duties of the gallbladder; diverticuli may appear, duct bile becomes static, new concretions form, and sooner or later the secreted bile dams back into the liver and biliary cirrhosis has begun. Deaver's biblical quotation is apt, but the title to his paper, *Operation and Reoperation for Gallstone Disease*, is still more apt, besides, the mortality table is not published.

Perhaps if the careful student of internal medicine adopts the motto, "Search and ye shall find," it may eventually be better for the patient, although the work may be slow and laborious and lacking in spectacular brilliance. One has only to peruse some of the better recent papers on gallbladder surgery to realize that operation means facing undeniable risks. Although the mortality has been steadily reduced it was nearly six per cent. in the thousand cases recently analyzed by Smithies (4), with thirty-five per cent. of associated pathological lesions of the upper abdomen found at operation, (enlarged lymphatic glands, acute and chronic pancreatitis, enlarged liver and peptic ulcer), indicating late diagnosis with well established pathological conditions. Added to this are the complications pictured by the surgeon, the skilled full time operator and not the occasional surgeon, of damage to the hepatic and common ducts, the recurring adhesions, the persistent fistulas, the oc-

casional fatal bleeding from the liver or from an accidentally torn blood vessel, the occasional traumatic puncture of the gut on the spilling of infective streptococci bile with resultant peritonitis, to say nothing of Nature's recurrent complications of new stone formation in dilated common ducts again obstructed, necessitating recurrent operations, and we have a true picture of the gallbladder problem as it stands in the light of our present methods of diagnosis and treatment. Certainly it is far better than it used to be, but is it as good as we can make it?

DESCRIPTION OF THE METHOD.

In order to present the method which I hope can be proved in other hands to possess the merits of early or late, direct diagnosis in gallbladder and duct disease, and of potential merit in the treatment of selected patients suffering from these diseases, I must go briefly into the fundamental principles which underlie the method. Much of this has already been presented in four previous papers on the subject (5, 6, 7, 8).

The biliary system consists of a constantly secreting organ, the liver, passing its secretion and excretion, the bile, down a series of tubes guarded at their terminal outlet by a muscle possessing a sphincter action. Placed between the liver and Oddi's muscle sphincter is the gallbladder with elastic walls permitting varying degrees of physiological distensibility, to act as a reservoir for excess bile secreted during the periods when the duct sphincter remains closed. Thus we have a mechanism that physiologically consists of the elaboration of a constantly secreted fluid, which, however, is discharged intermittently.

Upon what does the mechanism of partially or wholly emptying this biliary system depend?

Meltzer's law of contrary innervation (9) as he applied it to the filling and discharge of the gallbladder was briefly to the effect that the sphincter of the common bile duct and the muscles of the gallbladder were supplied with inhibitory and motor nerve fibres from the splanchnic and vagus nerves which acted antagonistically to one another. That when the inhibitory fibres relaxed the tone of Oddi's muscle at the sphincter of the common duct, the motor fibres to the gallbladder caused its muscle to contract and therefore discharge its stored up bile into the duodenum until such time as the sphincter would contract again, when, automatically, the inhibitory fibres to the gallbladder would cause a relaxation in the gallbladder wall, thus preventing a further expulsion of its bile and it would then resume its passive rôle of acting as a reservoir for the bile freshly secreted from the liver. Meltzer pointed out that the normal physiological stimulus to produce biliary discharge lay in the character of the food chemistry which passes through the duodenum. To establish this he quoted the experimental work of Bruns, which showed that normally no bile appeared in the duodenum as long as the stomach was empty, but that the entrance of a food chyme into the duodenum was the signal for the ejection of bile from the common duct. He further quoted the experiments of Rost who proved that injection of peptone or albumosis

through a duodenal fistula in a normal dog immediately caused a discharge of bile from the common duct and proved that this took place by a reflex act which caused a contraction of the gallbladder and simultaneously a relaxation of sphincter of the common duct. Furthermore, Rost had previously established the fact that after animal cholecystotomy the escape of bile through the papilla of Vater became continuous, whereas in normal animals it was discharged intermittently. This argued strongly in favor of Meltzer's law of contrary innervation in the fact that simple cutting into the wall of the gallbladder would destroy the antagonistic action of the nerve supply to the gallbladder and common duct sphincter. This mechanical breaking of the nerve circuit by operation can be easily demonstrated in postoperations in which the gallbladder has been either opened or removed, namely that bile is being discharged continuously into the duodenum so long as the common duct remains unobstructed. Furthermore, I believe this break in nerve conduction is mimicked in disease involving the wall of the gallbladder or in the wall of the duodenum adjacent to Oddi's muscle (duodenal ulcer, duodenitis, duodenal adhesions), because in this type of disease I frequently find continuous discharge of bile into the duodenum with a reflux of grossly recognizable bile in the fasting stomach in early as well as late pathological states of the duodenum and of the gallbladder. This observation of what is certainly pathological physiology appears to me to be a very important diagnostic factor in itself and useful because it may be indicative of early changes. The significance of fasting and digesting biliary regurgitation will be the subject of a future communication.

In regard to magnesium sulphate: Although Meltzer did not specifically state in his footnote that it would cause expulsion of gallbladder bile, but only that it would relax the duct sphincter, the inference was plain that if his law of contrary innervation was sound, anything which would cause inhibition of tonus of Oddi's muscle must, *ipso facto*, cause contraction of the gallbladder musculature. This is not so. Yet it is fortunate for the progress of this work that Meltzer was experimenting with magnesium sulphate for it will call into action this antagonistic or reciprocal action of duct sphincter and gallbladder.

But there are other substances (benzyl benzoate, belladonna, potassium permanganate), that will relax the duct sphincter and yet will not produce expulsion of gallbladder bile. Similarly there appears to be a selective gastric food chemistry that will electively cause expulsion of gallbladder bile in large quantities on the one hand and discharge of pancreatic secretion on the other. For instance, as Rost has already experimentally shown, peptones and albumoses (end products of acid gastric digestion), will call forth a richer and larger quantity of bile in the duodenum. This is seen in the proteid and fat test meals. Whereas, a carbohydrate meal, although bathed in the same acid gastric juice, will call forth more pancreatic juice and little, if any, gallbladder bile; although naturally the bile in the common duct and that secreted by the liver is being discharged during the time that

pancreatic secretion is being poured out. This appears to support the accepted theory of the physiology of automatic (or reflex) discharge of digestive secretions or enzymes according to the chemistry of the food stuffs to be digested. What the exact character of this mechanism may be, whether nerve reflex or blood reflex, or true harmonic action, or a mixture of them, will require further investigation both on animals and on human beings. But when we remember that the pancreatic duct and the bile ducts in ninety per cent. of anatomical subjects discharge their contents through a common ampulla governed apparently by the same sphincter, in each case the sphincter itself must relax to permit such discharge, yet the gallbladder may not necessarily contract each time, certainly not with the same degree of vigor. So it appears that while Meltzer's theory of the physiology of filling and discharge of the gallbladder bile is thoroughly worked out, and while his law of contrary innervation is substantially sound as regards magnesium sulphate (perhaps in this direct duodenal action a true hormone for gallbladder contraction), nevertheless there are certain substances, while they relax the common duct sphincter, have an elective action on the gallbladder or on the pancreas individually, and no doubt certain substances may have a dual action.

A great deal of this problem of physiology remains to be worked out before we can get away from a certain empiricism in the use of various diets and various drugs. The method of direct clinical investigation in health and disease by the duodenal tube, using various chemicals and food chymes, opens up a most attractive and profitable field of work.

To return to the subject of this paper. The method that I have suggested permits of making direct observations on the bile obtained from the several sources in the biliary tract.

To make possible accurate diagnosis of the duodenal biliary zone it is necessary that we adopt means to prevent cytological and bacterial contaminations from the mouth, teeth, tonsils, respiratory tract and stomach from confusing us in our interpretation of duodenal and biliary materials. To avoid this as far as possible I have adopted the following routine method in diagnosis. The use of proper apparatus will aid in the performance of good work. The patient presents himself with a twelve hour fasting stomach. He then brushes his teeth carefully, rinses and gargles his mouth and throat thoroughly, first with a strong solution of potassium permanganate (one grain to the ounce), then with a mildly astringent solution of zinc chloride. The duodenal tube which has stood overnight in a two per cent. solution of lysol is freshly sterilized by boiling and is passed to the stomach. The fasting residue is aspirated and set aside for chemical cytological and bacteriological examination for comparison with the findings later recovered from the duodenum. The stomach is then rinsed to sparkling clearness, using gravity douching from 250 c. c. irrigating tanks or syringe douching, and recovering the wash water in 250 c. c. conical graduates in which can be noted how clean the stomach is, mucus, shreds, mucopurulent plugs, and

other material which microscopically yields much valuable information. After the wash return is sparkling clear the stomach is made astringent with a zinc chloride solution (layoris), and then re-washed thoroughly. It is surprising to observe how often a stomach apparently washed clean, after being made astringent, will press out from the mucosal tubules mucopurulent masses which plug the ducts and which, microscopically, show, in true gastritis cases, masses of gastric epithelial cells infiltrated with small round cells and polynuclear leucocytes and often swarming with bacteria. It is to be noted that none of this epithelium is ever bile stained. After the use of the astringent and washing clean again, the stomach is then disinfected with 250 c. c. of potassium permanganate, one to ten thousand, which is immediately recovered and the stomach again washed clean to crystal clearness. This requires about twenty minutes to accomplish. This, so far as it is possible, prevents contaminated material from the upper zones confusing our interpretations of material later obtained from the duodenal biliary zone. After diagnosis has been completed and local treatment has been instituted it is not so necessary that preparation of the mouth and stomach should be so carefully carried out except when indicated in patients with dirty mouths and dirty stomachs. A little water is then left in the stomach to encourage peristalsis, the patient lies down and turns on his right side and very slowly swallows an additional twenty cm. of tubing to a total distance of seventy-five or eighty cm. from the teeth, according to the length of the thorax. I insist that they take twenty minutes to swallow the twenty cm.; slow swallowing at this point is often the secret of rapidly entering the duodenum. The duodenal tube is then connected to the first sterile aspirating bottle and the duodenal secretion is aspirated to note whether the common duct sphincter is normally closed. The duodenum is then douched with about seventy-five c. c. of a thirty-three per cent. solution of magnesium sulphate. This I believe to be the optimum strength for good sphincter relaxation and gallbladder contraction. Where the gallbladder is found atonic it is sometimes necessary to restimulate its contraction discharge by douching again with half the amount of magnesium sulphate solution.

Before the magnesium sulphate has entirely run in, the tubing is connected to the bottle and gentle aspiration started and the magnesium sulphate returns at first uncolored but within one to six minutes, normally, the sphincter is relaxed and the magnesium sulphate becomes tinged with bile, which becomes steadily deeper until pure bile alone is being recovered. Another bottle is then attached and observations are continued through the glass cannula window inserted in the tubing about eight meters from its proximal end. When the first bile, which I call A bile and believe to be that contained in the common duct plus a few drops from the cystic duct and a few mls, perhaps, of freshly secreted liver bile passing down the hepatic ducts, deepens to a distinctly deeper golden yellow or becomes in any way off color and more syrupy and

of heavier viscosity, this bottle is detached, another quickly attached and drainage of this darker bile allowed to continue until the third transition to a very much lighter yellow and thinner bile appears, when a final bottle is attached to continue the bile collection to the end of the drainage period.

The darker bile appearing in the second transition I call B bile and believe it to be derived almost entirely from the gallbladder, mixed, of course, with a few drops or mls of liver bile. My reasons for believing this bile to be gallbladder bile I have given at some length in a previous paper (8). The third type of very light yellow limpid bile which appears in normal cases in the third transition I call C bile and believe it to be bile recently elaborated by the liver cells and freshly secreted. It has invariably appeared at the termination of each drainage in nearly two thousand observations which I have made up to this time. Of course, one cannot hope to segregate these several biles absolutely unmixed with the other, but if one is careful in segregating them it is surprising how accurately they can be separated with a little practice, and I feel safe in saying that, if carefully done, the majority of A bile is common duct bile, that by far the majority of B bile is derived from the gallbladder and, if the latter has emptied completely, that practically all of C bile is freshly secreted liver bile.

(To be concluded)

WEIGHT, DIET AND EFFICIENCY.

BY ROBERT HUGH ROSE, M. D.,
New York.

This paper will discuss the following three subjects: 1, Undernutrition; 2, overnutrition; 3, intestinal toxemia.

The rôle of malnutrition as a factor in lessening efficiency has not escaped notice. Such cases are important; they have been given considerable attention, but are far more numerous than has been realized. Some persons through lack of appetite, are unaccustomed to eat a sufficient amount. Others, while they may consume an adequate quantity, do not choose a properly balanced diet. To bring the expenses within a certain income, the purchase of food is limited. Under these conditions the absence of a knowledge of food values may prevent the dietary from meeting bodily needs. The human body is the most efficient engine in the world. However, it can not operate without fuel, and its efficiency is limited by the fuel supply. Large employers of labor would do well to look into the matter of the proper feeding of employees in order to increase their efficiency. This could be accomplished by educational methods.

A class of cases receiving less attention but very frequently encountered and of great importance is composed of overnourished patients. Many sufferers from overnutrition also have autointoxication of intestinal origin, but there are some who have no indican in the urine and no sign by which the presence of an intestinal toxemia can be established. A third class of cases and probably the most numerous, consists of intestinal poisoning.

Very little will be said regarding the first class of cases because they have received wide discussion and there is little new to offer. I have treated a number of patients who were underweight and noticed that a gain of a few pounds was nearly always attended by an improvement in their general condition, increased energy and a feeling of well-being. An explanation which seems reasonable is that a change in diet sufficient to cause even a slight gain furnishes some reserve for the patient to draw on. Such patients, having lived on an insufficient diet, had no reserve, activity was reduced, and in all probability the metabolism of the body had adjusted itself so as to maintain the individual on a diet too low for the development of an average amount of energy. The increased diet changed the energy balance of the patient from negative to positive.

Cases of uncomplicated overnutrition undoubtedly exist. After a certain length of time complications occur, such as high blood pressure, fatty heart, and nephritis. But the patients become inefficient even before these complications develop. The effect of a weight reduction diet in such cases is sometimes much greater than would naturally be anticipated. The loss of a few pounds is followed by an improvement in breathing and relief from palpitation. The loss of such a moderate amount as ten pounds so markedly increases the ability to climb stairs that the patient speaks in no uncertain terms regarding the improvement. The following case well illustrates this point:

CASE I.—Mrs. J. S., aged fifty-three, housewife, complained of headaches, dizziness, fainting attacks (having fallen on the street on two occasions), and pain in the right arm. The patient was not constipated. Physical examination showed heart and lungs negative, urine negative, even to indican. Blood pressure 90-150. The patient began reduction diet March 21, 1920, her weight at that time being 197 pounds, 12 ounces; March 29th, weight 193 pounds; April 3rd, 191 pounds, 14 ounces, blood pressure 90-144. She had not fainted since starting treatment and the dizziness and rheumatic pains had decreased. On April 9th her weight was 190 pounds, 6 ounces. Patient stated that she climbed stairs more easily. On April 23rd, the weight had reached 186 pounds, 6 ounces. No fainting had occurred since starting the diet and dizziness was practically gone. No rheumatic pains remained and headaches were infrequent as well as trifling, though formerly they had been severe.

CASE II.—A case of obesity complicated by intestinal stasis, Miss B. M. K., aged forty, who began treatment on April 22, 1916. She had suffered from fainting spells, unaccompanied by pain or fever, and a feeling as if her "heart would stop." These attacks had been going on for two months. There was not much shortness of breath, bowels moved daily without medication. There was a bad taste in the morning, appetite good except during the attacks. Though the patient's bowels were regular, the stools were dark green at times, of offensive odor, and comparatively soft. Physical examination showed heart and lungs negative, blood pressure 150, slight tenderness over the right hypochondriac region. X ray examination by Dr. C. W.

Perkins indicated stasis due to adhesions between the colon and the gallbladder, the stomach being pulled to the right, the hepatic flexure of the colon held high, the ileum dilated and ptosed, bismuth being present in the cecum and ileum in the forty-eight hour plate. Colonic irrigations combined with *magnesia usta* by mouth and a weight reduction diet comprised the treatment. On April 22nd the weight was 184 pounds, 15 ounces. From the time treatment was instituted no further fainting spells occurred. On April 29th her weight was 182 pounds; May 27th, 172 pounds; June 23rd, 164 pounds; July 22nd, 150 pounds, 12 ounces. Blood pressure dropped to 120 by July 1st.

These two cases represent types of overnutrition causing inefficiency. The former patient was fast becoming incapacitated for her household duties, but within the short period of a month had reached an efficiency which was only slightly below normal. The second patient, a music teacher, was able, within two weeks, to resume her full duties, and lost no time thereafter.

The third class, intestinal toxemia, has been recognized for many years and has been treated with more or less success. However, a number of severe cases fail to receive the correct diagnosis and there are many mild cases that go unrecognized. These patients can never be properly treated until more attention is given to detail in diagnosis as well as in treatment. The dietetic management is not often sufficiently careful, and there is a tendency to relax it far too soon.

Indicanuria or scatol and indol in excessive quantities in the stool establish the diagnosis. The intestinal flora is never normal, the gram negative organisms (colon bacilli) being replaced in whole or in part by gram positive organisms. Constant absorption of toxins produces the symptoms found in such cases. The most prominent symptoms are lassitude, depression, feeling of melancholy, and inability to concentrate. The patients are frequently unable to attend to business, mental processes being almost suspended. When this condition has existed for a considerable time, kidneys, arteries, and heart are injured by the toxemia. A couple of cases may be cited to illustrate:

CASE III.—J. F., aged fifty-four, a heavy eater and drinker all his life, no headaches and appetite unimpaired. Several years previous to coming under my care depression had been extreme so that business was left entirely to assistants and retirement was intended. Examination of the test breakfast showed low values for free hydrochloric acid, the urine showed no albumin, sugar or casts, but large quantities of indican. The stools showed the following: Color, greenish black; odor, offensive; reaction, acid; indol and scatol were present in large amounts; meat fibres not normally digested, and bacteria almost totally gram positive. The treatment by irrigations, implantations of colon bacillus, the exclusion of meat and eggs and the prescription of milk as the chief protein food, did away with the indican and relieved all of the symptoms of which the patient complained. The patient's previously successful business life was resumed and conducted with unabated vigor.

CASE IV.—Mr. J. P. H., aged thirty-three. History of diarrhea while in the army. Since that time bilious attacks had been frequent and there had been complaint of nervousness, dizziness, lack of power to concentrate, depression, drowsiness and constipation. Stools were dark, almost black, offensive and hard. Examination showed the sigmoid and cecum not well emptied, the tongue was coated, indican five plus. The patient had been variously treated for nervous breakdown, constipation, and stomach trouble. The following treatment caused a quick improvement with a return to normal within six weeks. This patient was unable to perform the duties of his position at the time treatment was started, but he has worked steadily since going back during the sixth week. Meat and eggs were removed from the diet and milk substituted. Other articles of food were allowed freely. Cathartics to evacuate the colon more thoroughly were given and bacillus acidophilus was administered by mouth for months. Agar-agar, bran, Russian oil, and fruit are still being used, as the constipation is a difficult feature in this case.

Although there is nothing new involved in the diagnosis and treatment in the four cases cited, at least two of them had been unsuccessfully treated for a long time; one more than a year and the other for twenty years, and they represent a large class of patients going about from one physician to another, receiving various diagnoses, and generally grouped as neurasthenics. Whether these patients are ill through dietetic errors alone or have some mechanical condition, such as stasis, the control of diet is of prime necessity.

40 EAST FORTY-FIRST STREET.

ULCER OF THE ESOPHAGUS.

Diagnosis and Treatment.

By SAMUEL WEISS, M. D.,
New York,

Attending Gastroenterologist, Jewish Memorial Hospital.

Appreciation of the difficulties in diagnosing obscure conditions occurring in patients who complain of vague and indefinite sensations behind the sternum has prompted me to pay more attention to these symptoms with the express purpose of obtaining a more definite idea of the various underlying causes producing them.

Possibly none of the many striking conditions that are revealed by the x ray or the esophagoscope is so interesting as the demonstration of esophageal obstruction. A dogmatic positive or negative diagnosis is expected and is freely given by the radiographer, and is usually accepted by the physician, for it is a generally accepted axiom that it is a case of either guilty or not guilty, and that if the bismuth food passes freely down the esophagus there cannot be any obstruction. That is not the case, for obstruction is a relative term and depends on three distinct factors: 1, the consistency of the food in relation to; 2, the degree of obstruction, and 3, the power of the esophageal peristalsis, aided by the action of gravity.

Moreover it does not necessarily follow that an obstruction will always be present. Spasmodic contractions of the esophagus are just as frequent as in other parts of the alimentary tract. Where the mucous membrane is inflamed or ulcerated there will be a considerable spasmodic contraction that may, of itself, give rise to complete obstruction, although the underlying cause may be simply a small source of irritation. Perhaps the bismuth food allays the irritation and no obstruction is noted, whereas later a hard particle may set up the irritation and produce a spasm. The esophagus, unlike the rest of the alimentary tract, has approximately only one function, namely, to act as a highway from the mouth to the stomach, and anything that interferes with this function causes the symptom of esophageal obstruction, which may arise from a variety of causes. It is frequently the first and only sign of such serious conditions as new growths and aneurysms, while comparatively innocent lesions may produce the same trouble.

ANATOMY.

The description of the esophagus as a tubular organ of definite diameter is common in the books of descriptive anatomy. Like the rest of the alimentary canal it is a potential space when empty and is capable of considerable distention. The esophagus is divisible into three parts: 1, cervical, five cm.; 2, thoracic, eighteen cm.; and 3, abdominal, two to three cm. Clinically in the upper portion it is in relation to the trachea; at the level of the bifurcation of the trachea, to the left bronchus, the bronchial glands, the pleura, the pericardium and the recurrent laryngeal nerves; and lower down, below the bifurcation, to the aorta, and this is important. The diameter of the lumen increases on the average from above downward, varying from seven to twenty-two mm. Normally, certain constrictions occur at different levels. This narrowing is present at four points: opposite the cricoid cartilage; above the arch of the aorta; below the arch of the bifurcation of the bronchi, where it is crossed by the left bronchus, and at the diaphragm. Besides these there may be other points of narrowing which are without pathological significance.

On swallowing corrosive fluids, or when there is injury on passing esophageal bougies, the damage occurs most often at the level of one of these normal constrictions; scars are more common in these situations, and cancers also tend to develop in the same region.

In the anamnesis, difficulty in swallowing, pain on swallowing, a localized feeling of pressure in the course of the tube, or regurgitation of food makes an examination of the esophagus necessary. Dysphagia may set in suddenly or may begin insidiously and increase gradually. In esophageal stenosis, especially, the patients state that they have been compelled to use food of an increasing softness of consistency until finally only liquids could be swallowed. The patients either regurgitate food immediately, or they feel that it remains in the esophagus to be regurgitated later, perhaps in a decomposed, foul smelling state. Such patients emaciate rapidly. Where there is great variation in the ability to

swallow, a cardiospasm or a diverticulum of the esophagus may be suspected. Pain on swallowing may be sharply localized (ulcer, carcinoma), or may be diffuse throughout the whole length of the gullet (esophagitis). Regurgitation of food is characterized by the absence of hydrochloric acid; the reaction is usually alkaline and contains mucus. The most frequent location of esophageal ulcer, especially in males, is at the fourth constriction. About three quarters of all esophageal ulcers are found in this location. The next more frequent location is opposite the cricoid cartilage, and finally it is found in the narrowing where the left bronchus and aorta cross the esophagus.

The ulcers may be round, irregular or semicircular. In syphilis they are circular. Several ulcers may be found together or they may extend up and down the tube, or may occur at both ends of the esophagus. The right posterolateral wall seems to be a favorable site for ulcers occurring at the fourth constriction.

ETIOLOGY.

The etiology in many cases of esophageal ulceration seems to be obscure. Some of the probable causes may be: 1, pressure of the cricoid cartilage on the esophagus, or to pressure from a struma, an aneurysm, or a neoplasm; 2, in regurgitation of the gastric juice, to esophagomalacia or peptic ulcer; or 3, in esophageal varix to abrasion over the varix with formation of a varicose ulcer; 4, stenosis of the pylorus or duodenum or an hourglass stomach; 5, the intake of quantities of hot or cold food and hurried eating; 6, syphilis; 7, tuberculosis, malignancy; 9, swallowing of foreign bodies, as a fish bone or chicken bone, or piece of metal, may cause a scratch or erosion of the mucous membrane and generally ulceration; 10, injuries of esophagus in attempted suicide; ingestion of corrosive fluids.

SYMPTOMS.

The symptoms of superficial ulceration of the esophagus are insignificant. Usually in the long standing and deepseated ulcerations marked symptoms are produced. Difficulty in swallowing is present and is one of the chief symptoms in differentiating it from gastric ulcer. When a patient complains of pain immediately on swallowing and also has marked tenderness over the sternum, the internist should think of probable ulcer of the esophagus. Sometimes pressure over the lower border of the spleen may cause pain. On account of the difficulty in swallowing and because of the pain, patients often fear to take food, and become weak and emaciated; some have nausea, others vomit.

DIAGNOSIS.

The diagnosis in these cases depends upon the location of the ulcer, and we employ several methods which have their advantages and disadvantages. Röntgenoscopy and röntgenography of the esophagus will show whether or not there is a lesion or spasm and will guide us in referencè to employing a bougie. The use of the bougie should never be attempted unless the bismuth shadow shows a definite funnelshape at its lower end; a bougie may wander in an amazing fashion far away from the opening into the passage. Force must never be used, and even with the gentlest manipulation, a round-

nosed bougie may pass into an ulcer and down between the mucous and muscular coats, giving a sense of absence of obstruction.

Einhorn's string test for determining the location of the ulcer may give us little information, because not every ulcer bleeds, and even if it does, the thread may not come in contact with the ulcer and may mislead the internist who depends upon finding the red stain on the thread.

The most reliable instrument for making the diagnosis, locating the lesion and the kind of ulcer, is the esophagoscope. This instrument in the hands of a capable man is the most useful aid in diagnosing esophageal ulceration.

TREATMENT.

The treatment of esophageal ulcers, when properly carried out, yields gratifying results. I employ the duodenal tube for feeding, and give large doses of bismuth and magnesia by mouth. For the thirst a normal saline by rectum, preferably in the form of the Murphy drip, is given once or twice daily. The patient is kept in bed for the first few days, then he is permitted to get up, and for ten days or longer the tube is kept in the stomach and then withdrawn. The first two days after the tube is removed the patient receives milk with sweet cream and three eggs daily. On the third day, toast and butter and fine cereals are allowed. Should the symptoms recur when the patient goes on a more liberal diet, we go back to the fluid diet, and if that is ineffective another course of duodenal feeding should be inaugurated.

CONCLUSIONS.

In making a diagnosis it is the internist who is usually the first one to be consulted, and therefore it is his duty to analyze carefully the symptoms and determine the cause of the ailment. He should not merely tell the patient that he is nervous or some such makeshift diagnosis and prescribe a placebo. It is his duty to employ every available means to come to a definite diagnosis, and in many cases prevent future trouble. Should he be incapable of availing himself of the modern methods, it is no more than just that he refer the patient to someone who is able to employ the numerous diagnostic instruments and interpret the findings in a given case.

616 MADISON AVENUE.

PARIS LETTER.

(By our own correspondent.)

PARIS, May 30, 1920.

The Offensive of the Rockefeller Mission Against Tuberculosis.

If the Rockefeller Mission for the Prevention of Tuberculosis, instituted in Paris in 1917, fails to achieve the miracle of actually stamping out tuberculosis, it will at least have succeeded in an almost equally difficult task, viz., that of drawing together thousands of persons to Paris to hear lectures on the prevention of the disease.

In preparation for a recent gathering, M. Deschanel, President of the French Republic, and M. Léon Bourgeois, President of the Senate, were in-

duced to accept the honorary presidency of the convention, which was to be held on the heights of Ménilmontant, the extensive quarter of workmen's dwellings in the east of Paris. Some doubts had been entertained as to whether the affair would prove a success and the public take kindly to this new kind of propaganda. The meeting, however, was a splendid success. Although the daily press had hardly made mention of the proposed gathering, which was advertised largely by posters put up in the workingmen's quarter, the hall, accommodating three thousand persons, was completely filled, and hundreds had to remain standing.

The Ministry of Social Hygiene was represented at this gathering by M. Desmars, the chief of one of its services, who expressed the deep-seated gratitude to America felt by France for its campaign against tuberculosis and the large funds generously supplied for the purpose. "The Americans," he said, "have organized in France 108 dispensaries for tuberculous patients, arranged for a great number of lectures and motion picture demonstrations, saved hundreds of lives, and brought back hope to thousands of human beings afflicted with the dread disease." Special praise was bestowed upon Dr. Stewart, director of the propaganda against tuberculosis, and upon Mr. Bernard Wyatt, of New York University, who represented the Mission for the Prevention of Tuberculosis at the meeting.

Mr. Wyatt having thanked the speaker in a brief speech and made the statement that "everyone in America would be glad to stand by the side of our French friends in combating the disease," the floor was given in succession to the two main speakers, Dr. Bezançon, of the Académie de médecine, and M. Jean Blaize, special lecturer of the Mission for the Prevention of Tuberculosis.

"Tuberculosis," said Dr. Bezançon, "caused 86,113 deaths in France in 1911, these deaths constituting one tenth of the entire mortality in the country. To take effectual measures against it, it is necessary to be familiar with its causes and mode of development. Thirty years ago tuberculosis was commonly thought to be an inherited affection, and this idea is still entertained by a large number of persons. Already in 1865, however, Villemin, the French professor, maintained that tuberculosis was not inherited but was transmissible, and twenty years later this view was confirmed by the discovery of Koch's bacillus.

"Thus, the question as to the manner of preventing transmission of the disease presents itself. In this connection there is a great difference between tuberculosis and certain other diseases, such as measles and scarlet fever. Transmission of tuberculosis commonly occurs only after prolonged and repeated contact with a patient. The risk of transmission must, therefore, not be overemphasized, and it would be inhuman to insist upon complete isolation of consumptives, as has been the custom in the case of lepers. One need not hesitate to care for and bring cheer to a consumptive. Children, however, being extremely sensitive to the tubercle bacillus, must be carefully kept away from such patients. On the other hand, the risk of transmission among adults must not be overlooked." Dr.

Bezançon explained how uncleanness, unwholesome dwelling quarters, and badly planned workshops favor transmission of the disease. "We are constantly being told that tuberculosis is a poor man's disease. This is true only in that poverty compels families to live in overcrowded and dirty quarters, in close contact with patients who cannot be placed in isolation." Special stress was laid on the absolute efficacy of suitable prophylactic measures. The sputum being the vehicle of the tubercle bacillus, the main precaution consists in avoiding contact of any trace of the sputum with other persons. This precaution is one that can be instituted in a thorough manner, and in a well ordered sanatorium there has been no instance of transmission of the disease to any physician or nurse. In concluding, Dr. Bezançon spoke of the good work accomplished in the dispensaries and especially by the visiting nurses.

M. Jean Blaize spoke of various practical measures helpful in the tuberculosis prevention: Dry sweeping was condemned; curtains should be done away with; one should sleep with the windows open; tobacco and alcohol should be discarded; beans constitute a useful food. These various items of wholesome advice were delivered in such a manner and with such an unexpected choice of words that the listeners were moved to laughter every few minutes. Thus, speaking of tobacco, he said: "Tuberculosis, we are told, is transmitted by the sputum. But why do we spit? Spitting is a very unattractive habit. Women don't spit. Why not? Mainly because they don't smoke. Spitting is the privilege of men who smoke. The cigarette smoker spits a little. He is like the Petit Morin (a small affluent of the Seine River). The cigar smoker spits more, like the Grand Morin. The pipe smoker is like the Seine when it overflows its banks. The chewer of tobacco—he is like the Black Sea. Man is the only animal who smokes, and it is really America's fault, for it was Christopher Columbus who brought back the weed with him. Fortunately, at the present time the Americans are exporting habits of a different kind."

As was to be expected, the managers of the gathering also brought music and films into play. A complete Parisian regimental band played between the lectures. The most interesting film was that representing the open air school at Plessis-Robinson, a school originally of American conception and managed by the Bureau of Hygiene of the Department of the Seine. In this institution shelter is given to children predisposed to tuberculosis, and remarkable results have been obtained. The sight of these children playing or working in the open air, well cared for and watched, could not fail to encourage parents to separate themselves for awhile from their sickly offspring. Picture propaganda is highly effective.

The Ménilmontant gathering is to be followed by many others. The medical authorities are earnestly supporting the Rockefeller Mission. The large sums expended to insure continuity of endeavor are far from being wasted, and undoubtedly this first great meeting will be followed by material success.

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL

INCORPORATING THE

Philadelphia Medical Journal and the Medical News

A Weekly Review of Medicine.

Address all communications to

A. R. ELLIOTT PUBLISHING COMPANY,
Publishers, 66 West Broadway, New York.

Subscription Price: Under Domestic Postage, \$6; Foreign Postage, \$8; Single copies, fifty cents.

Remittances should be made by New York Exchange, post office or express money order, payable to A. R. Elliott Publishing Co., or by registered mail, as the publishers are not responsible for money sent by unregistered mail.

Entered at the Post Office at New York and admitted for transportation through the mail as second class matter.

NEW YORK, SATURDAY, JULY 3, 1920.

NOTICE TO OUR READERS.

The index to Volume CXI of the New York Medical Journal will be printed separately. Copies of this index can be obtained by writing to the editorial department.

PUBLISHER'S ANNOUNCEMENT.

At no time since the founding of the NEW YORK MEDICAL JOURNAL in 1843 has the situation in regard to publishing been so acute. The prices of printing and paper have gradually risen and in many departments expenses have increased three fold during the past four years. Some months ago we were confronted by a strike of the printers, but at great expense and trouble, not to speak of loss, we brought out the JOURNAL with regularity, never missing an issue. Following this there was a shortage of paper, due to a tie up of transportation facilities, and again we published the JOURNAL without the loss of an issue. We transported paper by automobile from a great distance. In spite of these difficulties this service was maintained for our readers by a constant struggle.

Through all these adverse circumstances we have constantly been improving the quality of the JOURNAL, making it of ever increasing value to our readers. Our special correspondents in foreign countries have been on the alert for papers by European workers, so we could keep our readers informed of the latest advances in science across the sea.

We have established a department of book reviews, for which we secure the services of workers in the various fields of interest to the physician. This department has proved to be a guide to the medical men in this country. We had felt for some time prior to establishing this department that too little attention had been given by medical journals to the textbooks of medicine. In these books are usually found the most careful work of men in medicine, frequently the consummation of years of study and work. In comparison with the space given to hurriedly written papers, frequently a rehash of things published many times before, and to extemporaneous remarks at medical meetings, under the head of proceedings of societies, books received scant consideration.

We arranged special numbers of the JOURNAL in order to group together under one cover the latest findings of leading medical men in each particular specialty. These numbers are of distinct service, rendering easily available information concerning a special subject for which one may be looking. So far we have had special numbers devoted to endocrinology, neurology, gynecology, the alcohol question, dentistry, diabetes, ear, nose and throat, and gastroenterology.

In order to keep things moving and carry out our policies we shall reduce the size of the JOURNAL slightly during the months of July and August, resuming the normal size with the first issue in September. There will be no reduction, however, in the amount of original material. The high standard set for our department of book reviews will be maintained. The special numbers will be continued. The material which we shall present will be chosen with great care and only those things which we believe will be of interest to the medical practitioner will be given space.

THE SYMPTOMATOLOGY OF VOLVULUS OF THE CECUM.

The onset of volvulus of the cecum occurs in one of two ways; the process either commences suddenly with violent abdominal pain and colic, accompanied by vomiting, or, more commonly, the patients are constipated and suffer from abdominal pain, particularly in the right iliac fossa where true paroxysms of colic are complained of. These premonitory phenomena, the result of movable cecum, are generally regarded as due to the appendix.

The pain in volvulus is intense, all the greater the tighter the constriction. It may be continuous,

but usually it takes the form of colic, recurring in paroxysms at the time of intestinal contraction. As the evolution continues the intestine becomes distended, paralysis of the gut ensues, abolishing peristalsis. The colic then decreases progressively and is replaced by a more fixed pain, due to beginning peritoneal reaction. The pain is usually situated rather low in the right iliac fossa, but its site varies, and it has been known to occur in the hepatic region or on the left side. In these cases the location of the pain was due to a complete dislocation of the cecum.

The pain extends progressively throughout the abdomen, to the back and sacral region. It is spontaneous, but the patient can lessen it by changing his position. Abdominal palpation does not usually reveal any point of exacerbation, and in fact little can be ascertained by it. The patients compare the pain to deep crushing or a sharp constriction within the abdomen.

Vomiting appears soon after the onset of the pain and is almost always a constant symptom, statistics showing that it is absent in only ten per cent. of the cases. It may come on as late as twenty-four hours after the onset of the abdominal pain, but this is exceptional, and persists with tenacity, although some instances have been recorded where it temporarily subsided or even completely disappeared. It is interesting to note that the vomiting is not free, as in other types of intestinal obstruction, and it is rarely fecaloid.

The immediate consequence of volvulus is an arrest of the feces and gas, and this is likely to be complete from the start; but there are a few exceptions to the rule. When once the obstruction is realized the lower portion of the large intestine may empty itself, spontaneously or otherwise, but only during the first few hours following the volvulus. The paresis of the large intestine is the factor of its reflex paralysis.

The pain which existed at the onset declines little by little, but when the paroxysms have subsided a new symptom appears, namely, abdominal distention, which renders the peristalsis more clearly visible. This distention appears as soon as the pain and vomiting have subsided and reaches an enormous degree, but its principal characteristic is that it is distinctly localized in the region of the volvulus, because an abundant exudation of fermentable fluid takes place at that point which results in the production of a considerable quantity of gas. The site of the distention varies; it may occur in the peri-umbilical region or in the left hypochondrium. In one case it formed a sonorous oval tumor, similar in shape to an ovarian cyst. Occasionally the tym-

panic area encroaches upon the umbilical region and becomes evident in the right hypochondrium. As operations have shown, the fundus of the cecum is above and to the left and ascites is present, usually in so small an amount that it cannot be detected clinically. When present, it is a cloudy or frankly hemorrhagic fluid. Such are the symptoms peculiar to volvulus of the cecum. The general symptoms, such as the pulse, and normal or subnormal temperature, are the same as those encountered in any kind of intestinal occlusion.

THE CHOLESTERIN CONTENT OF THE FECES.

The study of the cholesterolin content of the feces is interesting because it forms a necessary complement to the study of cholesterolin in the bile. In the feces it is no longer found in the form of cholesterolin but largely in the form of a product of reduction, namely, coprosterin. The study of cholesterolin in the feces cannot *a priori* furnish any indication relative to that of the bile, because it is now a well established fact that the cholesterolin thrown into the intestine by the bile is in large part absorbed by the intestinal epithelium. The knowledge of this important datum is due to the splendid researches of Dorée and Gardner. They first showed that what was formerly designated under the name of hippocoprosterin is nothing else than phytosterin which passes untransformed in the intestine of the horse. As far as the cholesterolin thrown into the intestine by the bile is concerned, the feces of this animal do not contain a trace. Continuing their researches in the dog they note during different diets that the quantity of cholesterolin eliminated by the feces of the animals was invariably inferior to that which is normally thrown into the intestine by the bile. They, however, remarked that this fecal elimination of cholesterolin, very minute with a diet poor in cholesterolin—bread, cream and white of egg—is notably higher following a meal rich in cholesterolin, such as brains.

The fecal cholesterolin is above all the result of the quantity of cholesterolin entering into the composition of the food ingested. It is largely composed by the more or less considerable portion of cholesterolin in the food consumed which has escaped intestinal absorption. In reality, the cholesterolin ingested with food is not integrally absorbed by the intestine. During their experiments on rabbits, dogs and cats Dorée and Gardner observed an absorption of from forty to sixty per cent. of the total cholesterolin contained in the food. Chasoburo

Kusumoto came to similar conclusions and showed the influence of diet on the quantity of cholesterol eliminated by the feces. Klein has also pointed out that intestinal absorption is not more pronounced with the ethers of cholesterol than with free cholesterol and that in all circumstances the presence of fats is necessary. The more recent elaborate and remarkable experiments carried out by Grèze confirm in general the findings and conclusions of the former observers.

CHOLESTERINEMIA IN DISEASES OF THE LIVER.

As is known, hypercholesterinemia is absent in the hepatic cirrhoses and congenital or acquired hemolytic icterus likewise undergo their evolution without an increase of cholesterolinemia and this is still another element which opposes the hemolytic jaundice to all other kinds of icterus. On the other hand, Grigaut has found hypercholesterinemia frequently in those states which accompany disturbances of the biliary secretion and here, as in cases of Bright's disease, it may attain very high percentages, as much as fifteen grams to the litre.

A certain relationship exists between the percentage of the cholesterolinemia and the intensity of the reaction of the other elements of the bile. For example, in catarrhal icterus the hypercholesterinemia, cholemia and bilirubinemia usually follow a parallel evolution. This does not occur of necessity and there are numerous cases in which there is a dissociation between the retention of cholesterol and that of other elements of the bile—bile salts and pigments. It is known that during cholemic states the bile salts and pigments may be retained independently from each other in the organism and a similar dissociation occurs between bilirubinemia and cholalemia. It is the same for hypercholesterinemia which, although appearing generally in subjects accompanied by cholalemia, may nevertheless be met with outside of any bilirubinemic or cholalemic states, thus constituting an isolated state of biliary retention. This is what is encountered in lithiasic and xanthelasmic states where a marked hypercholesterinemia may exist without any jaundice being evident.

Inversely, in icterus from retention, hypercholesterinemia may be absolutely wanting regardless of the intensity of the bilirubinemic or cholalemic retention. The dissociations thus observed, even in icterus from retention, between the constituent elements of cholelentic states cannot be explained by a simple mechanical phenomenon which obstructs the flow of bile at some part of the liver, but supposes

an active interference of the hepatic cell in every case. This is an important point as regards the part played by the hepatic cell in the metabolism of cholesterol.

One of the clinical consequences of hypercholesterinemia in hepatic subjects is the xanthelasma which until recently has been empirically attached to cholemia but in reality, as Chauffard and La-roche have shown, is directly related to an increase of the cholesterol in the serum. The nodules formed by the fatty ethers of cholesterol which are observed to develop in icteric and diabetic subjects are due to a deposit in the skin of the cholesterol in excess in the blood.

A marked hypercholesterinemia is likewise at the bottom of biliary lithiasis and Chauffard has shown the importance belonging to this hypercholesterinemia in the pathogenesis of this other local deposit of cholesterol. The relationship between cholelithiasis and pregnancy and typhoid fever can be explained by the hypercholesterinemia. Let it be added that the hypercholesterinemia which is usual in cholelithiasis is an excellent differential sign for the diagnosis of doubtful forms of biliary lithiasis.

THE PRESENCE OF HEAVY METALS IN FOOD.

An occasional sensational headline in the papers about a man having died through eating copper, creates the impression that in most canned or preserved food there lurks mortal poison. But the important fact should be noted that the heavy metals are well borne for a long time if taken with food, indicating the intestinal canal exerts a protective action against the metals and their salts. Yet, disturbance of function of the intestinal canal or structural changes of the mucous membranes of stomach and intestines may occur; the protective action of these organs may cease and the metals thus gain access to the different organs, causing serious damage.

According to recent analyses, the quantity of zinc in oysters may reach 1.15 gm. to the kilo; in baker's yeast 0.414 to the kilo. Dried eggs may have 2.4 gm. to the kilo. Copper in oysters varied between 52 and 53.9 a kilo; canned vegetables may have up to 2.75 gm., 0.25 gm. of nickel sulphate may be present in green peas. Tin has been found up to 10 to 450 mg. to the kilo. Lead is often present in small quantities.

Dr. Salant, writing on this subject in the *Journal of Industrial Hygiene*, June 1920, says that: "The unreflective will point out the very small quantities ingested. The analysts admit this, but produce cumulative evidence of the harm from small quantities frequently taken into the system, and at any rate, the public is entitled to the benefit of the doubt in the case of metals the entire harmlessness of which rests in the fact that no sure results have been obtained."

News Items.

Bequests to Hospitals.—By the will of William F. Armstrong, the Methodist Episcopal Hospital, of Brooklyn, will receive \$25,000 to establish William O. Armstrong beds; the General Hospital Society of Connecticut will receive \$25,000, and the Bridgeport Hospital, \$10,000.

Coordinating Child Health Work.—The American Red Cross announces that a council of coordinating child health activities has been formed. The societies represented in the council are: American Child Hygiene Association, American Red Cross, Child Health Organization of America, National Child Labor Committee and the National Organization for Public Health Nursing.

National Association for the Study of Epilepsy.—At the nineteenth annual meeting of this association, held recently in New York, Dr. G. Kirby Collier, of the Craig Colony of Epileptics, Sonyea, N. Y., was elected president, succeeding Dr. L. Pierce Clark, of New York. Dr. Joseph J. Williams, of Woodstock, Ontario, was elected vice-president, and Dr. Arthur L. Shaw, of Camden, N. J., was reelected secretary-treasurer.

New Dean of Yale School of Medicine.—Dr. Milton C. Winternitz has been elected dean of the Yale School of Medicine, to succeed Dr. George Blumer who resigned recently. Dr. Winternitz was graduated from Johns Hopkins University in 1903 and served on the faculty for some time. He joined the Yale faculty in 1917 and during the war was in charge of research in pathology and bacteriology at the University for the Bureau of Mines.

Personal.—The honorary degree of doctor of science was conferred upon Mr. Herbert C. Hoover by Tufts College, at the annual commencement held on June 21st.

Dr. H. Violle has been appointed by the League of Red Cross Societies as medical liaison officer between the central committee of the French Red Cross, the League of Red Cross Societies, and the French Ministry of Health.

Dr. Richard P. Strong, of Harvard University, chief medical officer of the League of Red Cross Societies, has been elected to honorary membership in the Serbian Medical Society.

New York and New England Association of Railway Surgeons.—The thirtieth annual session of this association will be held at the Hotel McAlpin, New York, on Tuesday, October 19, 1920, under the presidency of Dr. William B. Coley, chief surgeon of the New York Central lines. Special effort is being put forth by the officers to make this one of the most successful meetings of the association. An attractive program is already nearly completed. Dr. George W. Crile, of Cleveland, has accepted an invitation to deliver the address in surgery, and other leading surgeons will read papers. Two chief claims attorneys will present papers, and the president of an Eastern trunk line is expected to be present and address the members of the association. Dr. George Chaffee, of Binghamton, N. Y., is corresponding secretary of the association.

Dr. Hyslop's Brain.—Dr. James H. Hyslop, a well known psychologist and editor of the *Journal of the American Society for Psychological Research*, died at his home in New York on June 17, 1920, of cerebral thrombosis, and his brain was given to Dr. Edward A. Spitzka, of New York, for scientific study. The brain had not been weighed on removal, but when received by Dr. Spitzka, after five days' immersion in five per cent. formaldehyde solution, its weight was 1,290 grams, or 45.5 ounces avoirdupois.

Medical Museum Congress.—The thirteenth annual meeting and exhibition of the American and Canadian Section of the International Association of Medical Museums was held April 1st and 2nd at Cornell University Medical College, in conjunction with the meeting of the American Association of Pathologists and Bacteriologists. The meeting was under the presidency of Dr. O. Klotz, of Pittsburgh. Officers elected for the ensuing year were as follows: President, Dr. W. M. L. Coplin, Philadelphia; secretary treasurer, Maude E. Abbott, Montreal; assistant secretaries, L. Gross, Montreal, and H. Goldblatt, Cleveland.

American Laryngological, Rhinological, and Otological Society.—At the annual meeting of this society, held in Boston, on June 2nd, 3rd and 4th, the following officers were elected: President, Dr. Lee Wallace Dean, of Iowa City, Iowa; vice-presidents, Dr. Harmon Smith, of New York, chairman of Eastern Section; Dr. Joseph C. Beck, of Chicago, chairman of Middle Section; Dr. Joseph B. Greene, of Asheville, N. C., chairman of Southern Section; Dr. William V. Mullin, of Colorado Springs, Colo., chairman of mid-Western Section; Dr. Hill Hastings, of Los Angeles, Cal., chairman of Western Section; Dr. Ewing W. Day, of Pittsburgh, Pa., treasurer; Dr. William H. Haskin, of New York, secretary; Dr. George L. Richards, of Fall River, Mass., chairman of Publication Committee. The next annual meeting will probably be held in Atlantic City, N. J., somewhere about the first of June, 1921.

Plague in America.—In accordance with forecasts made by the United States Public Health Service over a year ago, bubonic plague has made its appearance in the United States. At present, foci of the infection are known to exist at New Orleans, Pensacola and Galveston, and in Tampico and Vera Cruz, Mexico. In Vera Cruz, the disease appears to have assumed the proportion of an epidemic. Calling attention to this outbreak of plague and renewing his warning regarding the introduction of plague from Mediterranean ports which are known to be infected, Surgeon General Hugh S. Cumming urges communities throughout the country, and especially along the coast, to inaugurate rat extermination and ratproofing campaigns. With the definite knowledge now possessed regarding the transmission of this disease, and especially as to the rôle played by rats, the situation should cause no alarm or panic among the people of this country. Nevertheless the very real menace of bubonic plague calls for an energetic campaign of extermination directed against the rat, and other rodent pests.

Book Reviews

TEXTBOOK OF PHYSIOLOGY:

A Textbook of Physiology. By RUSSELL BURTON-OPITZ, S. M., M. D., Ph. D. Illustrated. Philadelphia: W. B. Saunders Company, 1920. Pp. v-1185.

This work, which appeared recently, takes a prominent place in the literature of medical physiology. It is a valuable book of reference for the medical student or the physician who has maintained his interest in physiology. The essential point in which this book differs from others of its type lies in the emphasis which is given to the clinical aspect of the subject. It is not a book for the research worker. On every page there is evidence that it was written specifically for the clinician.

The work is arranged in logical sequence, treating in turn the various physiological functions of man. There is enough discussion of comparative physiology to give the reader some idea of the wide application of physiological laws. The essential propositions are stated with brevity and simplicity, although in the more general discussions one is led into rather deep waters. There are many references to physiological literature, and the work of the older foreign physiologists especially is cited. Numerous diagrams and illustrations form effective graphic expositions of the written text. The tone of the book is conservative. The physician who is too busy with his practice to keep abreast of the ever increasing literature of experimental physiology, but who desires to keep in touch with the standard physiological doctrines, will do well to refer to this book.

BACTERIOLOGY.

Pathogenic Microorganisms. By WILLIAM HALLOCK PARK, M. D., Professor of Bacteriology and Hygiene University and Bellevue Hospital Medical College and Director of the Bureau of Laboratories of the Department of Health, New York City, and ANNA WESSELS WILLIAMS, M. D., Assistant Director of the Bureau of Laboratories of the Department of Health; Consulting Pathologist to the New York Infirmary for Women and Children. Assisted by CHARLES KRUMWIEDE, JR., M. D., Assistant Director of the Bureau of Laboratories; Assistant Professor of Bacteriology and Hygiene in the University and Bellevue Hospital Medical College, New York City. Seventh Edition. Enlarged and Revised. Illustrated. Philadelphia: Lea & Febiger, 1920. Pp. iii-786.

This book is the outgrowth of the original first edition which was called *Bacteriology in Medicine and Surgery*. Since the publication of this unassuming first edition much progress necessitated many changes in the editions that followed. This, the seventh edition, presents new phases of the work done on media. Dr. B. v. H. Anthony has written the chapter and he has incorporated the work done on hydrogen ion concentration. Many other important chapters have been revised including those on streptococci, yeasts, and the influenza bacillus. The entire question of immunity is presented in a lucid and well written manner and this alone would commend the book to the practical worker. The nucleus of the book originated in the bacteriological laboratories of the city of New York. The authors have been successful in presenting the ordinarily dry subject of bacteriology in a way that is understandable and useful to the general practitioner.

THE ART OF PRESCRIBING.

L'Art de prescrire. Par le Professeur GILBERT, professeur de clinique médicale a l'Hotel-Dieu de Paris, Membre de l'Académie de Médecine. Paris: Librairie J. B. Baillière et Fils, 1920. Pp. x-373.

This book is no simple compilation, no mere cookbook collection, but is *L'Art de prescrire* and an attempt has been made to change this dry science and make it charming and attractive. Professor Gilbert, lecturer at the Hôtel Dieu, Paris, has been rendering the subject of prescribing interesting to his students for many years. The General Principles of Therapeutics is a fine, lucid exposition; this is followed by a chapter on official remedies, and their efficacy according to mode of usage, many warnings being given as to haphazard treatment. The patient is always considered as an individual first. The supplement has an historical note on the origin of recipe, on tables of solubility, and the incompatibility of certain drugs, and will be useful to those who do their own dispensing. He is wise on not going deeply into the question of psychical agents in such a book, but, as he says, every good doctor is unconsciously a psychotherapist. "The doctor's speech, his pious lies both help to raise the listless *morale* of a patient. The sound of his voice, his look, his smile, his mere presence bring joy and hope and favor a right action of the treatment he prescribes."

POSTMORTEM TECHNIC.

Postmortem Manual. A Handbook of Morbid Anatomy and Postmortem Technic. By CHARLES R. BOX, M. D., B. S., B. Sc., Lond., F. R. C. P. Lond., F. R. C. S. Eng.; Physician to St. Thomas's Hospital and to the London Fever Hospital; Late Demonstrator of Morbid Anatomy, St. Thomas's Hospital. Second Edition. Illustrated. London: J. & A. Churchill, 119. Pp. vi-372.

A concise, practical manual, dealing with the gross pathological changes to be found at autopsy. The descriptions of the various technical steps are of practical value and their observation would prevent the mutilation so often encountered, due largely to lack of training on the part of the operator. Many short cuts are given and these too should save time and energy. Many useful hints are scattered throughout the text. To take advantage of these would save many a tyro from embarrassing experiences. The simplicity of the style and the direct handling of the subject make it an easy book to study.

ARTERIOSCLEROSIS AND HYPERTENSION.

Arteriosclerosis and Hypertension. With Chapters on Blood Pressure. By LOUIS M. WARFIELD, A. B., M. D., (Johns Hopkins), F. A. C. P. Formerly Professor of Clinical Medicine, Marquette University Medical School, etc. Third Edition. Illustrated. St. Louis: C. V. Mosby Co., 1920. Pp. xv-265.

In no field of medical endeavor has more work been done than in the study of the baffling subject of hypertension and arteriosclerosis. As the author says: "Much that has been written on the subject is of little value." It is yet a bit early to determine just how much value there is to anything that has been written on the subject. The topics have been approached from many angles and much information

secured, but for the major part we are still very much in the dark. None the less we are obliged to make the most of the material we have at hand. Warfield has approached this complex subject with great candor and has only presented the findings of which he is reasonably sure. He has carefully avoided the presentation of the many involved theories which have been the ground of so much serious controversy and has clung to the pathways of empirical medicine. With fearlessness he has presented his own findings and these appear to be rational enough. Where he has lacked boldness, he has made up in good sense. Many will disagree with him but all will respect the sincerity with which he has given his findings to the medical profession. It is a comfort to find a book on any subject which is not a rehash of all that has gone before on the same subject. The technic of blood pressure observation during anesthesia at operation is simple and it seems as though this method should be used more generally as it is a valuable guide in operative procedures. Aside from this as an aid to research work valuable data could be obtained.

MANUAL OF ANATOMY.

Cunningham's Manual of Practical Anatomy. Revised and Edited by ARTHUR ROBINSON, Professor of Anatomy in the University of Edinburgh. Seventh Edition. In Three Volumes. Illustrated. New York: William Wood & Co., 1919.

There have been no changes in this standard anatomy since 1914. Three impressions were taken of the sixth edition which first appeared at this time. Many new changes and additions have caused the publishers to publish the book in three volumes in place of the usual two, Volume I includes the superior and inferior extremities; Volume II, the thorax and abdomen, and Volume III, the head and neck. As the book stands today it is considered one of the most valuable class room dissecting manuals.

CHRONIC DISEASES.

Origine, évolution et traitement des maladies chroniques noncontagieuses. Par J. DANYSZ. Paris: Librairie J. B. Ballière et Fils, 1920. Pp. vii-130.

For many centuries the list of incurable diseases was very long and a chronic invalid was accepted without question by the family: nothing was done except to render his battered tent as impervious to disease as possible. In fact, an invalid was supposed to exert a good moral influence by his patience in suffering and claim to self-sacrifice on the part of relations.

But inspired by success learned men no longer tolerate chronic maladies, but fight them, and among the cheerful hoppers of ultimate victory is Professor Danysz, of the Paris Pasteur Institute, whose studies have led him to the conclusion that all chronic morbid conditions, with their acute crises and more or less prolonged intermissions, have antigens as origin, and, as determining cause, the state of anaphylactic immunity of the organism. Experience has shown that antianaphylactic treatment has incontestable efficacy in all chronic maladies, except in purely mental ones, and even these are being effectively studied. Results have been obtained by

nonspecific antigens, to explain whose curative action the author and his collaborators have been forced to admit the direct and predominating intervention of the nervous centres on the curative reactions. There is a capital résumé, followed by an exposition of the general theory of immunity, anaphylaxis, and antianaphylaxis based on the structure, properties, the functioning of the organism, its structural units and the functions of which it is composed.

MEDICAL EXAMINATION OF AVIATORS.

Guide pratique pour l'examen médical des aviateurs, des candidats à l'aviation, et des pilotes. Par Le Dr MAUBLANC et le Dr. RATIÉ, médecins du centre d'aviation de Chartres. Préface de M. le Dr. ANDRÉ BROCA, professeur agrégé à la Faculté de Médecine de Paris. Illustrated. Paris: Librairie J. B. Ballière et Fils, 1920. Pp. vi-109.

In the beginning the airman's wings were pluck and experience. War made urgent demands: the men flew to fulfil them, but often came hurtling to the earth, bruised, dying, because of some little fault in their physical or mental condition.

The present year has brought time for a scientific examination of all government aviators, and few of them will be properly grateful to Maublanc and Ratié for their splendid guide, simply because much stress is laid not on present physical condition but on past history. Yet to men so highly placed as examiners, attention must be given. The apparatus they use admits of no argument on the part of the candidate, the wicked machine heartlessly records its findings.

They reject all who have had bacillosis long ago, or recently, pleurisy, scarlatina, articular rheumatism, syphilis, or malaria, wounds which have left functional impotence if this impairs them as pilots, slight cardiac lesions though there seem to be perfect compensation at the time of examination. All suffering from tuberculous affections, of whatever degree, must be rejected, also the dyspeptic, nephritic or enteritic. "Who then can be saved?" ask the rejected. We refer them to the excellent guide whose writers declare as their object the raising of the military status of aviators and bringing about that appreciation by the public now so heavily lacking.

NOW IT CAN BE TOLD.

Now It Can Be Told. By PHILIP GIBBS. Illustrated. New York: Harper & Brothers. Pp. iii-558.

During the long anxious years of the war we read with interest the dispatches of Philip Gibbs, correspondent. Some of us, the more or perhaps the less fortunate, who saw and felt some of the things he was writing about, realized at the time that he was telling the truth—that is, as much of the truth as could be told.

Now he has told us the story all over again. The officers who in the former dispatches were gallant men now have their stupidity revealed; they are no less gallant in the new picture but the picture is completed. We are told again of the heroism of raw recruits, how they stormed the trenches, and yet in their hearts they had no hatred for the much advertised Hun. He shows how similar in appearance the captured boys were to the boys who captured them; only by their uniforms could they be

told one from the other. He makes it seem as though they came from the same common stock, that they were brothers in more than appearance, settling the quarrels of short sighted rulers who followed old traditions which had long since become useless except as a means of perpetuating their own worthless class. The men tell us, in this document of Gibbs's, that they did not want to kill Germans. They had no quarrel with them and they didn't like the work of butchery.

He shows how in the actual combat the men were swept off their feet and the lust for killing arose in them in an atavistic fashion. The men harked back to the old barbarities; the old savage, sadistic instinct came to the fore; they went back to their archaic past, to their embryonal, infantile state. We see how the propaganda of blood curdling tales of cruelty, tales from Belgium of children's hands cut off, old men murdered, and women violated, sent the men hurrying to the army. We now see the unraveling of the red tape of the staff and the suffering red dawns with the closing red toll. And we better understand the fear the censor had in not allowing the truth to be told; a fear of their own people, not of the enemy, for the enemy knew. In a graphic way we are made to realize by a few cold words how the old professional army came to die and how modern warfare opened the battlefield to the multitude. There could no longer be a group watching the paid gladiators. . . . If there must be war then they must all share in its sacrifices. . . . There would have to be victims as well as victors. Names appear, spelled in full, initials included, and the owners are given full credit for their sins, both of omission and of commission. No one escapes in this fearless telling, not even the commander in chief of his own army—the British.

It took courage to tell the story and it has great value, for no one can doubt the authenticity of an accredited man like Gibbs. He was there. He saw it and now when we can sit back in a relaxed frame of mind we will do well to hear what he has to tell.

It may be said that we are weary of war and stories of war, but we who were through what some are pleased to call the great adventure, see it in another light. We can more truly call it the great crime, or many more harsh sounding names. It may be that we have had enough war. We did have a great deal of it and it was a bit of a war—but too little has been told—too little of the truth. The books have told us more of the heroics and less of the cold, beastly, mechanical grind of the whole maniacal business. Too little of the diabolic mess and too much of the heroes. The more we read of true stories such as this the less war we will have to write about in the future.

This book will take its place with Zola's *Downfall*, Andreyev's *Red Laugh*, Barbusse's *Under Fire* and Latzka's *Men in War*.

Gibbs is bitter in his denunciation of militaristic intervention in Russia. He states that England and France stood by when the old Tzardom with which they had allied themselves committed every type of cruelty against a helpless people, and when these people founded a new order, which was more dangerous to the old order than high explosives, they attempted to crush their newly won liberties. He

tells how the French mutinied and how the British soldiers themselves would not go to Russia.

The beauty and truth of his closing lines allow for their repetition. "Now let us exorcise our own devils and get back to kindness toward all men of good will. That also is the only way to heal the heart of the world and our own state. Let us seek the beauty of life and God's truth somehow, remembering the boys who died too soon, and all the falsity and hatred of these past five years. By blood and passion there will be no healing. We have seen too much blood. We want to wipe it out of our eyes and souls. Let us have Peace."

SCIENCE IN FICTION.

The Golden Scorpion. By SAX ROHMER. Illustrated. New York: Robert M. McBride & Co., 1920. Pp. v-308.

The writers of stories of mystery and crime in 1920 do not meet such responsive thrills as heretofore. The improbabilities of an earlier age are probabilized. Verne and Haggard would be certified as sane by any alienist, and so eager are writers to show their prescience that they despise the steady radiance of accepted science and pen their stories by the as yet uncertain light of marvels to be revealed.

But, on the whole, we are grateful to Sax Rohmer and his kind for leading us away for awhile from those facts "which every woman—every man should know," and introducing us to *The Golden Scorpion*, whose real name is Fo-Hi and who is so intimate with radium and really scientific methods of getting rid of enemies. There is a doctor, too, superhuman in his knowledge of poisons, human in his knowledge of women, and triumphant in saving the heroine Miska from the fiendish Fo-Hi. We are rather sorry when "there came a flash of blinding light, an intense crackling sound, the crash of broken glass, and a dense cloud of pungent fumes rose in the heated air," because that means the story is finished. "The complete and instantaneous disintegration (of Fo-Hi) had taken place," the marvelous suicide resulting from his researches.

THE ETERNAL QUESTION.

Women's Wild Oats. Essays on the Refixing of Moral Standards. By C. GASQUOINE HARTLEY. Author of *The Truth About Women*, *Motherhood and the Relationships of the Sexes*, etc. New York: Frederick A. Stokes Company, 1920. Pp. vii-227.

Over two thousand years ago, three young men of the Persian Royal Guard were keeping watch one night in the King's antechamber. There had been a banquet that night; plenty of wine and beautiful women, and perhaps they found it difficult to keep awake, so to pass the time they got up a competition. They would each write on a piece of paper that which they esteemed the strongest thing in the world and put the slips under the King's pillow. In the morning he would find them, and, to the wisest writer he would be asked to accord the award—an award of privileges and gifts.

But, when they were read, King Darius sent for the royal staff and said the young men should defend their own statements and those of the Court should decide. The first had written: "Wine is the strongest." The second, "The King is the strong-

est." The third, "Women are the strongest, but, above all things, Truth beareth away the victory."

Each statement was eloquently defended," and the King and the princes looked one on another perhaps approvingly) for women had a good advocate, but suddenly the defender boldly said, "Wine is wicked, the King is wicked, women are wicked. . . . as for the Truth, it endureth and is always strong: it liveth and conquereth for evermore." A bold statement, when it was not wise to displease a King and pretty ladies were influential at court and delighted then, as now, to bewitch men with their "tinkling ornaments, chains and bracelets and ornaments, changeable suits of apparel, mantles and wimples and crisping pins," and the Piccadilly and Broadway ladies of those days lurked in dusky corners to beguile young men at night. There was a moment's silence, then a mighty shout went up from all present. The speaker had a Kingly kiss and cousinship bestowed, and far more—politically—than he had dared to hope.

Gasquoine Hartley is one of a large throng who are earnestly trying to write the wisest thing. She has studied women all through the ages, and, while admitting that education, suffrage, larger views, and war times have changed woman's position and relegated many oldfashioned views to the lumber room, her descriptions and opinions as to moral worth might be embodied among those of prophets and reformers thousands of years ago.

But she frankly admits that old world cures will not cure, and has plenty of sympathy for the new girl. She deals ably with the question of woman's fitness for work, for her home duties, her attitude toward marriage and lover, the unmarried mother and the love child, divorce, and platonic attachments. The young guardsman who won the royal kiss also spoke frankly concerning the ways of women. What does the author suggest? It is hardly fair to pick out sentences without giving the context, but a few gleanings may draw more attention on the part of readers to a closer study of the whole.

"There are many without the gifts that make for successful parenthood or happy permanent marriage. I would recognize this frankly and let those who do not desire marriage be openly permitted to live together in honorable temporary union . . . those who do not want children and, not wishing the bondage of continuous companionship, desire to pass their lives in liberty."

"The essential fact in every relationship of the sexes is the woman's power over the man, and it is the misuse of that power which leads to all prostitution. For the lust, men are held responsible: the chaste character of women held up in contrast! This view gives women all the pleasing satisfaction of a virtue that is realized without effort and explains why they object to repressive measures.

If we inquire into this question of men's lust, it is obvious that not they, but women, are the more responsible. Man's lust is a necessity to her very existence. She is the controller of the assault."

The foolishness of allowing the fallen girls to bring up their babies, and of continuing in un-

happy wedlock all have stormy comments. Again we ask with her, "What is the cure?" but, unlike her, we shout "Truth is the strongest." People do not abuse the moribund. The still active, open hostility to vice exposure or to changing customs shows vigilant interest, an undying interest, for, as far back as written pages tell us, zealous men have found that women are decadent, rapidly going to the devil, enemies of men, and in no age have been as bad as the present (their own day). A sorry lookout for the men, seeing that woman stands at the very gate of Life and all men must humbly enter by her permission.

Meanwhile sex literature is flooding the market. It is a case of "secrets known to all," but, to our mind, the life, not the writing, of one good, open minded loving woman deters more girls from evil than any amount of books. No antivice remedy will be curative when administered in the septic, battered spoon of pessimism. Good is stronger than evil. Wine is strong, the King is strong, women are strongest, but, above all things, Truth beareth away the victory."

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE LIGHT HEART. By MAURICE HEWLETT. New York: Henry Holt & Co., 1920. Pp. xii-188.

THE PROBLEM OF NERVOUS BREAKDOWN. By EDWIN LANCELOT ASH, M.D. New York: The Macmillan Company, 1920. Pp. xii-299.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Surgical Intervention in Severe Forms of Dysentery.—Jacques Leveuf and Georges Heuyer (*Paris médical*, April 10, 1920) state that in acute gangrenous dysentery associated with grave symptoms, immediate rest for the ulcerated intestine by surgical means is indicated. Diverting the course of the fecal flow also permits of intensive feeding and of bringing about direct remedial action on the colonic lesions through appropriate lavage. A broad cecostomy opening, readily made and constituting a harmless operation, answers the requirements and yields highly gratifying results. In chronic cachectic dysentery—essentially a protracted gangrenous dysentery—the same indications obtain; the main aim should, however, be to prevent such a condition by insisting upon early operation. In cases of dysentery distinctly improved by ordinary measures but not cured within a reasonable time, appendicostomy followed by intestinal lavage is a useful adjunct to the medical treatment. Cecostomy should be considered an emergency operation, having precise indications which hardly permit of temporizing. Appendicostomy brings to medical treatment the added assistance of the direct action of lavage on the proximal portion of the colon.

Treatment of Acute Intestinal Intoxication with and without Acidosis.—J. S. Weitzel (*Virginia Medical Monthly*, March, 1920) states that in the acute intestinal intoxication of young children, prevalent during the summer and early fall months, an initial dose of two to four drams of castor oil should be given unless there is persistent vomiting, in which case sodium bicarbonate should be begun at once and given in sufficient doses to keep the urine alkaline. If, however, the bowels have been very active and only serum and mucus are being evacuated, the initial cathartic is unnecessary. If vomiting continues after administration of sodium bicarbonate, one or more stomach washings with bicarbonate solution will usually allay it. A colonic irrigation of warm saline solution once or twice a day proves highly beneficial in these cases. But little pressure should be used, and the tube should be inserted for a distance of four or five inches. Bismuth subcarbonate, ten grains every three hours in children under six months of age and every two hours after six months, until some astringent action is noticed, is occasionally beneficial. Paregoric should be used only to relieve tenesmus or when large watery stools persist, and should not be given in doses large enough to produce stupor. In cases with severe prostration, brandy, caffeine sodiobenzoate, and camphor in oil are satisfactory stimulants. When acidosis arises, sodium bicarbonate must be given promptly, either by mouth, subcutaneously, or intravenously. By mouth, fifteen to thirty grains every two hours should be given until the urine is alkaline, and then enough to keep it alkaline. Subcutaneously a two per cent. solution, and intravenously a four per cent. solution, are

used. Boiling of the solution during its preparation must be avoided. The intravenous method in infants with an open fontanel is very satisfactory, and is simplified by use of the Goldbloom needle for injection into the longitudinal sinus. In severe forms in which the intake of water is greatly reduced and the tissues become relatively dry owing to the frequent watery stools, intraperitoneal administration of normal saline solution is the most efficient corrective procedure. A spinal puncture needle is inserted through the abdominal wall in the linea alba, one half inch below the umbilicus, and the warm saline allowed to flow in by gravity to the amount of seventy-five to 150 mils, according to the size of the child. The procedure is repeated daily until the tissues lose their dry, parched appearance and the doughy consistency of the abdomen disappears. After the initial rest of the stomach, protein milk should be used to feed the child.

Late Results of Appendectomy for Chronic Appendicitis.—Enriquez (*Bulletin de l'Académie de médecine*, March 16, 1920) asserts that in over one fourth of all cases, appendectomy for chronic appendicitis fails to benefit the patient. Surgeons have often found, in addition to appendiceal disease, such conditions as adhesive pericolicitis, more or less pronounced omental inflammation, cecum mobile, and kink of the distal loop of the ileum. Often constipation is more obstinate, painful attacks more frequent, and nausea a more marked feature, than before the operation. In one group of cases there is pronounced impairment of the general condition, with anemia and slight vesperal fever, ultimately ascribed, as a rule, to a latent pulmonary or lymphatic tuberculous process. Spontaneous pain, or pain induced by certain postures, radiates toward the umbilicus, liver, or right lower extremity. Tenderness is greatest between the operative scar and the umbilicus, and palpation may give the impression of rigidity, a cord, or even a tumor in this region. In a second group of cases fever is wanting, but digestive symptoms are more marked, viz., late pains and eructations, and constipation interrupted by mucomembranous diarrhea, occurring in attacks preceded by severe headache. To forestall such attacks the patients reduce their diet and ultimately pass into inanition, with the accompanying asthenia, depression of spirits, and hypochondria. General visceroptosis is the rule in these cases, with gurgling in the cecum and painful spasm of the descending colon. Radioscopy yields definite findings in these two groups of cases. In the first, the stomach is tonic or hypertonic, and its axis no longer vertical; the hepatic flexure is drawn toward the midline; the ascending and transverse colons are in apposition; the lower portion of the cecum fails to ascend in the horizontal posture, and there is delayed evacuation of the ileum. In the second, the stomach is hypotonic or atonic; there is coloptosis; the cecum is very movable, and the Lane kink is present. In

the first group the disturbance is mainly inflammatory; in the second, mainly mechanical. In both instances the blood shows a leucocytosis of 10,000 to 14,000; the large mononuclears are increased to ten to fourteen per cent., and the eosinophiles, to three to eight per cent. The main difficulty is that heretofore chronic inflammation of the appendix has been regarded as constituting practically the whole of the pathology of the right iliac fossa. The remedy is routine x ray examination, which will reveal the various coexisting lesions requiring special surgical procedures if recovery is to be obtained. The physician should himself be present during the radioscopy, and not rely on plates alone. Examination in both the standing and the recumbent postures are essential. In operating the surgeon should make incisions sufficiently long to permit of the necessary exploration of the ileocecal region, cecum, hepatic flexure, and omentum. Where the symptoms suggest a gallbladder, pyloric, or duodenal lesion, the McBurney incision may be advantageously replaced by Walther's median incision, or better, the transverse supraumbilical incision employed by Gosset.

Enterostomy for Postoperative Intestinal Obstruction.—A. S. Brinkley (*Virginia Medical Monthly*, February, 1920) emphasizes the harm done by extensive operative manipulations in these cases and recommends, instead, enterostomy through a small incision under local anesthesia. Morphine is given hypodermically half an hour before the operation, a McBurney incision usually made, and one half of one per cent. novocaine solution used to infiltrate the tissues. After thorough infiltration of the preperitoneal fascia the peritoneum is incised and a quick exploration carried out with the middle and forefingers to locate if possible the point of obstruction. Then a loop of intestine nearest this point on the proximal side is brought up and an enterostomy done on the principle of Coffey, viz., of forming a valve of the intestinal mucosa. After packing around the loop with gauze moistened in saline solution, an incision about two inches long is made with a sharp knife down to the mucosa. A purse string suture of linen is placed at one end and the mucosa within the grasp of this suture punctured. A soft rubber catheter is quickly inserted through the puncture, the purse string tied snugly, an end of the suture threaded in a sharp needle, and the catheter transfixed and held in place. The portion of the catheter over the incision is then buried with a right angled suture. The bowel is sponged off with saline sheets and returned to the abdomen, and the wound closed with interrupted through and through silkworm gut sutures. The catheter stays in position at least five or six days, and when it is removed there is little or no leakage of fecal contents; the mucous membrane is thin, pours out but little plastic exudate, acts readily as a valve, and tends to close the opening. Gastric lavage with soda solution is ordered every four to six hours until no longer indicated. Saline solution with glucose and soda is given by rectum every four hours. Hypodermoclysis is also practised and caffeine sodiobenzoate or digalen given if the heart action is not good. The catheter is connected with a longer tube and the drainage collected in a bottle

tied to the bed rail. Every two or three hours the catheter is disconnected from the longer tubing and about one ounce of warm water is injected into the bowel, to keep the catheter open. All feeding is withheld for at least forty-eight hours, then liquid nourishment given every two hours for the next five or six days. Mineral oil, one ounce three times a day, is started on the fifth or sixth day, and enemas given according to indications. The catheter could usually be removed in five to seven days, but the author leaves it in for ten days. Three cases of postoperative intestinal obstruction dealt with by this method are reported. All the patients recovered and left the hospital in from three to six weeks after the operation. One of the patients was a woman seventy years of age.

A New Vehicle for Emetine Bismuthos Iodide.—T. J. G. Mayer (*Journal of Tropical Medicine and Hygiene*, May 1, 1920) states that he has found a new vehicle for this compound which will pass through the stomach unchanged and be digested by the intestinal juices. The drug is rubbed up with sixteen parts of mutton fat, the mass moulded into rounded pills weighing about seven grains, and each pill covered with a layer of mutton fat, applied with a paint brush. The mutton fat being solid at body temperature, it is not digested until it is too far beyond the pyloric orifice to be regurgitated and cause vomiting or even nausea. Pills containing one and a half grains of the drug and about seven and a half grains of mutton fat are about as large as may be conveniently swallowed. Two were given each night for twelve consecutive nights. The pills were kept in the ice chest but the addition of thymol might serve instead as preservative. That the emetine bismuthos iodide was altered by the intestinal juices was shown by the discoloration of the feces and the cure of the dysentery.

Kaolin as a Substitute for Bismuth Subnitrate.—Hayem (*Bulletin de l'Académie de médecine*, April 13, 1920) states that while bismuth subnitrate taken on an empty stomach in the morning in a single large dose of twenty grams is the remedy par excellence for gastric pain of any variety, and is free from the risk of alkalinophagia which attends the use of sodium bicarbonate, a salt of good quality is now hard to obtain, and the price of bismuth salts has so increased as to render them unavailable to a large proportion of patients. In 1915 he tried kaolin as substitute in a case of gastric ulcer, and found it so satisfactory that he has more recently been using it in all the varieties of cases in which the bismuth salt is generally given. The kaolin as administered is an impalpable powder consisting of silica, alumina, and the oxides of iron and magnesium. It is practically insoluble in water and the organic fluids. Well washed kaolin is almost tasteless and may be given with water like bismuth. The same dose is used. As kaolin is somewhat lighter, at least a half hour should be allowed to elapse after the dose before breakfast is taken. To provide a pleasant flavor, one half drop of oil of anise may be mixed in each twenty gram powder of kaolin; or, one third drop of oil

of peppermint may be used instead. Like bismuth subnitrate, kaolin acts as a disinfectant and deodorant to the stools; in fact, it is even preferable to bismuth in its effects on the bowel, tending to allay intestinal disturbances and regularize intestinal action. It should not be looked upon as a complete substitute for bismuth subnitrate, as its effects are less regular and sustained. It is, however, remedially sufficient in many cases. Internal use of kaolin has already been recommended by others in Asiatic cholera and chronic diarrhea, but the writer claims priority in pointing out its property of relieving pain, as well as of acting as disinfectant, in gastroenteropathic patients.

Gastric Secretions in Neurocirculatory Asthenia.—John H. Musser (*American Journal of the Medical Sciences*, May, 1920) says that in patients suffering with neurocirculatory asthenia there is a very definite increase in the total acidity and free hydrochloric acid as compared with controls. These figures do not represent abnormal hyperacidity, but they do show that almost uniformly soldiers suffering from neurocirculatory asthenia as contrasted with apparently normal soldiers, both eating the same food, under identical routine and under the same conditions of living, show a higher gastric acidity. This is a diagnostic point which may be of value in differentiating the disorder in questionable cases. It surely seems to add further evidence to that already accumulated that these soldiers are suffering from a neurosis with which is probably associated a hyperirritable agus.

Percussion in the Detection of Tender Points in the Abdomen.—G. Hayem (*Bulletin de l'Académie de médecine*, February 24, 1920) emphasizes the necessity of establishing a clear clinical distinction between pain and tenderness in abdominal disorders. Induced pain is a better term than pain upon pressure, for tenderness may be elicited by means other than pressure. The author uses special percussion hammers with gauges showing the force of each blow delivered, from fifty up to 1,000 grams. When the customary tender points are tapped with this hammer, patients with abdominal disorders are found very sensitive to the procedure. Sometimes even very light percussion will bring out tenderness at points previously found insensitive to firm pressure; this occurs especially in cases in which the abdominal muscles are contracted. In gastropathic patients the tender points are nearly always the same. One is situated on the linea alba, somewhat nearer to the xiphoid than to the umbilicus. One or two other sensitive points along the linea alba are not infrequent, and such points should also be examined for both to the right and the left of this line. Sensitive points can often be detected along the right costal margin, but are exceptional on the left side. In many patients apparently free of intestinal disorder, and even oftener in those actually suffering from such disorder, percussion over the colon is more or less painful, especially over the cecum, transverse colon, and sigmoid. Tenderness to percussion or pressure is sometimes of neurotic nature, and may relate to a dermatalgia or neuralgia—with or without central neurosis. It may

also be of muscular origin. Generally, however, it results from organic disturbance. Most recent authors ascribe it to sensitiveness of the abdominal nerve plexuses, but it is actually difficult to exert effective pressure on these plexuses, and under ordinary circumstances, especially when percussion is used, the pain induced can only be visceral in its location. At the point of election above the umbilicus the tender point may be situated in the peritoneum, the liver, or the stomach wall at the lesser curvature. Aside from ulcer and cancer cases, the ordinary pain of dyspeptics is probably in most instances localized in the liver, at least, pain on percussion is elicited nearly always over the portion of the liver covering the upper portion of the costo-umbilical triangle. Since tender points are often found simultaneously along the right costal margin and along the course of the large bowel, it seems justifiable to conclude that in chronic gastric affections remote reaction upon the liver and bowel is a frequent accompaniment.

Results of Operations for Chronic Appendicitis.—Charles L. Gibson (*American Journal of the Medical Sciences*, May, 1920) recommends the following in order to avoid disappointing results, basing the suggestions on a study of 555 cases: 1. A comprehensive and detailed history. 2. A complete and thorough physical examination, including all refinements of diagnosis. 3. Exercise caution in undertaking operations on women as compared to men. 4. Exercise caution, particularly in the more mature patients, particularly women; in this class other lesions may coexist or may be mistaken for appendicitis. 5. Avoid the neurasthenics of any age or sex. 6. Exercise particular restraint when there is no clear and reliable history of well defined attacks, particularly of localized pain accompanied by nausea and vomiting. 7. Make a good sized incision, and, even if a frankly pathological appendix is found, look for other possible lesions. 8. If no obviously pathological appendix is found, do not cease looking for other lesions until every other possibility has been exhausted.

The Calorie as a Unit in Figuring Milk Modifications.—Tracy Jackson Putnam (*Boston Medical and Surgical Journal*, January 29, 1920) asserts that the method of calculating milk modifications according to the absolute caloric values of the respective food elements is as rational as the present methods of calculation by percentage composition and volume, or by total caloric value. The use of the calorie as a unit in expressing the composition of milks is of advantage in that all food elements are reduced to a common standard. Such a view of infant's diet, he thinks, might lead to a clearer comprehension of the subject by some practitioners. It would allow of easy manipulation of the fluid volume apart from the food value of various mixtures, and might lead to the accumulation of more data concerning the effects of alterations in fluid volume, and would facilitate the extension of the calculation of the diet into late infancy when desirable. He believes that the calculation of modifications would be simpler in many ways, and more easily understood, than many of the present systems.

Miscellany from Home and Foreign Journals

Acidosis in Acute Abdominal Disorders.—M. Lablée (*Bulletin de l'Académie de médecine*, April 6, 1920) maintains that acidosis is a condition of broad clinical interest and value and should be systematically investigated in all patients, like albuminuria and glycosuria. He is in the habit of applying the Gerhardt, Legal, and Lisben tests for this purpose. While relatively uncommon in the major acute infections, acidosis is frequently present in acute inflammations of the abdominal organs, e. g., in appendicitis, cholecystitis, salpingitis, etc. In appendicitis of intermediate severity or with peritonitis it is present in a majority of cases during the acute stage, disappearing after a few days but recurring if a relapse occurs. It is particularly marked in some cases without very high temperature but with probable involvement of the liver. The same condition appears in salpingoophoritis with pelvic peritonitis, and especially in cholecystitis and pericholecystitis. Fasting, operative trauma, and anesthesia are not important factors in the acidosis in such cases. Its main cause is functional disturbance of the liver secondary to the infection. Evidences of hepatic insufficiency generally coexist with the acidosis. Generally there is an intense urobilinuria, which dwindles and disappears along with the diaceturia. With H. Bith, Labbé found ammoniuria and aminoaciduria in cases of appendicitis, even in the presence of slight acidosis. In a case of abdominal infection during pregnancy and in one of fatal acute hepatic insufficiency in a pregnant woman, he found in conjunction with positive acidosis tests, a marked aminoaciduria and all evidences of insufficient proteolytic activity.

Chronic Digestive Disturbances in Gas Poisoning Cases.—Maurice Loeper (*Bulletin de l'Académie de médecine*, March 2, 1920) states that poisoning with chlorine or mustard gas causes chronic digestive disturbances oftener than poisoning by pallete or benzyl bromide. Such disturbances are met with in about six per cent. of the chlorine and mustard gas cases. The flatulent type of disturbance is characterized by anorexia, gas accumulation, discomfort soon after taking food, and aerophagia; the painful type, by late pains and symptoms generally suggestive of pyloric disease. The chief pathological disorder produced is probably a pyloritis. There is often salivation, nausea, and vomiting. Either hypochlorhydria or hyperchlorhydria may be present, the former due apparently to deep initial involvement, with mucous atrophy, and the latter to more superficial disturbances, with secretory functional reaction. That the condition is a gastritis and not a simple dyspepsia is confirmed by cytological examination of the stomach contents. In one form, such examination reveals a marked desquamative gastritis; in the other, the presence of large numbers of polynuclear leucocytes or lymphocytes, indicating a persistent infection of the mucous membrane. The epithelial desquamation often coexists with increased gastric acidity; the diapedesis, with lowered acidity. These local changes produce secondarily

an abnormal sensitiveness of the abdominal nerve plexuses, low blood pressure, disturbances of cardiac rhythm, and variations in the oculocardiac reflex. Tenderness occurs not only in the celiac region but also in the superior and inferior mesenteric and the iliac regions. The pulse is often slowed, or may be irregular and with premature beats. Pathological studies showed in three cases the presence of microscopic hemorrhages in the stomach wall nine, twelve, and sixteen months, respectively, after the poisoning. No true ulcer was seen, but two cases showed permanent deformity of the greater curvature, and one case, partial stenosis of the pylorus—all ascribable to the marked lesions induced at the onset.

Gastrointestinal Service in an Army Hospital.—John A. Kantor (*Military Surgeon*, May, 1920) states that too pessimistic an impression as to the capacity of dyspeptics to qualify as fighting men is by no means justifiable. Now that such evidence is available, more than one ex-soldier will bear witness that his dyspepsia disappeared almost completely during his period of service. There is indeed no way of telling in advance in many an instance whether the disability is such as to be benefited or aggravated by military duties. The policy pursued in the recent mobilization of assigning trained men as gastroenterologists to the various base and general hospitals is decidedly to be recommended. Such men can readily build up special services that will be properly equipped to dispose adequately of all cases showing digestive disturbance. By this means much time can be saved in the weeding out of the absolutely unfit, the distribution of the moderately disabled to restricted duties, and the cure of those suffering from transient disorders.

Diverticulitis.—G. G. Turner (*Lancet*, January 17, 1920) reports several cases of diverticulitis, one with so great a thickening of the intestinal wall that a new growth was diagnosed at operation; another at the sigmoid flexure with a similar hyperplasia of the gut wall and a perforation just above it through which a large gallstone had ulcerated, and a third in which a very small almost isolated diverticulum had perforated producing a peritonitis. The etiology is considered by this author to be congenital. The diagnosis must be made on a history of repeated inflammatory attacks extending over long periods. This will help in differentiating from new growth after the inflammation has produced the thickened tumorlike mass palpable through the abdominal wall. As for treatment, the writer has had success with temporary colotomy to rest the bowel, with subsequent resolution of the inflammatory process so that the colotomy wound was closed and the lower part of the gut was able to function again. He has also inverted the projections converting them into polypi, with satisfactory outcome. It is important to keep the bowels regular and to have the patient stop eating when symptoms develop, if medical treatment is used.

Congenital Anomaly of Duodenum.—Leonard Freeman (*Surgery, Gynecology and Obstetrics*, May, 1920) states that partial occlusion of the duodenojejunal angle, simulating pyloric obstruction, occasionally occurs from the persistence of a condition normally existing in fetal life. In this, the duodenum, instead of appearing in the abdominal cavity from beneath the transverse mesocolon to the left of the spine, as it should, emerges to the right, its transverse and ascending portions possessing a peritoneal covering and mesentery of their own, similarly to the rest of the small intestine, instead of being fixed in fibrous tissue, as is normally the case. At the duodenojejunal angle, however, the bowel is hung up to the root of the colonic mesentery by a firm adhesion (duodenal fold of fetal life), the kink thus produced being intensified by the downward pull of the free duodenal loop. This kink is deeply situated and in freeing it care must be taken not to injure the bowel, the inferior mesenteric vein or the left colic artery. A considerable denudation of the gut may be necessary, which should be covered either by reuniting the peritoneum or by means of a free omental graft.

Nonrotation of the Colon.—Dudley Roberts (*American Journal of Surgery*, June, 1920) discusses the association of obscure abdominal symptoms with nonrotation of the colon and presents his conclusions as follows:

1. It seems probable that the anomaly is not as rare as might be inferred from the scarcity of literature. The condition is easily overlooked even at operation and many of the cases have not been reported.

2. Failure to locate the cecum in its usual site should immediately arouse a suspicion of nonrotation especially if small intestines present themselves in the right iliac fossa. Most frequently the cecum will then be found low down in the midline, even in the pelvis. Less frequently it will be found high in the middle of the abdomen, under the liver or in the left iliac fossa.

3. Left sided or midabdominal pain with symptoms suggestive of appendix inflammation suggests the advisability of a röntgen examination which will positively demonstrate the site of the cecum.

4. Erroneous conclusions may be reached in a röntgen study of these cases, particularly if the failure of rotation is only partial and the cecum is found on the right side of the abdomen. If the end of the cecum is seen pointing upward or inward the inference might be drawn that one is dealing with a lesion and not an anomaly.

5. The fact that sixteen cases out of twenty-two collected from the literature showed appendix inflammation associated with symptoms regarded as sufficient to justify operation suggests that nonrotation increases the natural predisposition to pathological conditions in the appendix. While this is not a proposition that can be proven it tends to justify the inference that we are dealing with an abnormal appendix when in a proven nonrotation case there are obscure abdominal symptoms. Certainly exploration of the appendix should be performed even if another incision is required for the purpose.

Letters to the Editors.

MORPHINE POISONING.

BROOKLYN, April 28, 1920.

To the Editors:

The recent report in the newspapers that a boy had died from the effects of swallowing morphine recalls a case which came to my notice forty years ago and which shows that morphine poisoning need not be fatal if the proper remedy is applied.

A physician who wanted to commit suicide gave himself 120 subcutaneous injections of one sixth grain of morphinum sulphurium each, or a total of twenty grains. He was soon found in a comatose condition, and a physician was immediately called. He sent for three others, among whom I was one. As morphine kills by paralyzing the respiratory centres, we at once undertook artificial respiration. We first removed the patient's clothing and two of us, one standing on each side, effected inspiration by the usual method of raising the arms high above the head, and expiration by lowering them and pressing them firmly against the thorax, the other two of us resting in the meanwhile. The patient's pulse was a little weaker and slower than normal. We had no time to take the blood pressure or make other observations. The only symptoms other than the lack of respiration were the contraction of the pupils—greater than I had ever seen before—and, of course, complete muscular paralysis. Occasionally we would stop for a few seconds to see whether he could breathe by himself, but he could not. Only after we had worked over him for eight hours did respiration begin, and then irregularly. After an hour more of partial continuation of our work he breathed fully and regularly, opened his eyes and spoke. He soon recovered completely, and after some weeks took up his practice again. His case indicates that the mortal effect of morphine is but a paralysis of the respiratory centre.

CHRONIC INTESTINAL TOXEMIA.*

A Study Based on One Thousand Cases.

BY ANTHONY BASSLER, M. D.,
New York.

Professor of Gastroenterology, Fordham University Medical College
and New York Polyclinic Medical School and Hospital.

It gives a feeling of satisfaction to have worked on a subject in any of the learned sciences and then to see an awakening of interest in it even though this may take years to come about. Ten years ago no work worth while was being done on intestinal toxemias. A paper of mine at the time (1) received no recognition until recently, and now many men are at work on a subject that unfortunately is far from simple and requires much careful study. There have been debates back and forth, definite attitudes for and against certain aspects of the subject, but the consensus of belief of the best workers, is that such conditions exist, and that food and bacteria make up the important etiological factors in their production and therapeutics. These may have been my beliefs for the past ten years, during which time many cases have been diagnosed and treated on these bases. The clinical material comprised in all of these cases is too voluminous from which to make deductions, so, the last thousand cases have been taken and the best possible brief deductions made from them.

As pointed out by me, chronic excessive intestinal toxemias should be divided into two main groups, primary and secondary. The secondary are those that are due to intestinal anchorings from adhesions or bands, angulations, ptoses, specific infections within the gut in which the toxemia is part of a mixed infection (such as tuberculosis, syphilis, streptococcal infections of the buccal or nasal cavities, typhoid carriers), parasitic conditions, advanced age, neglected routine of life, habitual constipation, and other conditions. Some of these patients may require surgical treatment, others medical treatment. It is in the secondary toxemias that surgery often plays an important part, not the sort of surgery that Lane advises, but such surgery as is logical and safe. I do not believe that a chronically diseased appendix ever causes a secondary toxemia, because it is the toxemia that causes the disease of the appendix, and almost the same thing may be said of the gallbladder, but not

so definitely. I am of the opinion that colitis, whether sectional or general, has four causes, more or less mixed in parts, in all cases. These are unfortunate heredity and improper early life, endocrine disturbance, a neurological tendency, and a chronic intestinal toxemia. Such conditions always demand medical treatment and while conservative surgery may be required to do away with conditions that come secondarily, this is often only incidental.

Primary intestinal toxemia, which is most frequently encountered, is a biochemical change from normal digestion in the intestinal canal. It takes place in the contents of the small intestine rather than the colon, although most frequently its whole process is installed in the ileum and in the colon to the hepatic flexure. In my opinion, it is entirely bacterial in nature. Whatever the food, whatever any other condition, it is the change from a normal bacteriology of the intestinal canal that figures most prominently as the cause. An examination of specimens of the stool will prove this, but the analyses must be more complete bacteriologically and chemically than those done in laboratories today. Examination of the urine may or may not be valuable; with normal urine the stool specimen often will be positive. To mention all the laboratory technic and findings in this work would be most uninteresting and out of place in a short paper like this. It would require a great deal of space and is obtainable by a study of the literature and by laboratory practice. It is more interesting to speak of the cases from a clinical viewpoint. Clinically and confirmed by laboratory the cases occurred as follows:

Secondary toxemia.—Definite anchoring of the gut, 27; intestinal obstruction (incomplete), 19; carcinoma, 14; marked ptosis, 62; tuberculosis, syphilis, etc., 20; nasal and buccal infections, 91; parasitic infections, 43; definite gut infections (specific), 6; neglected routine of life, 69; other causes, 30; total, 381.

Primary toxemia.—Putrefactive (indolic), 180; fermentative (saccharobutyric), 172; mixed form, 224; definite streptococcal or staphylococcal, 43; total, 619.

Although a little theatrical and somewhat overdrawn, Lane's description of the chronic gut case is the best in the literature. He did not distinguish between secondary toxemia, in which conservative surgery might be required, and the primary forms. All was grist to the mill for his propaganda. But

*Read by invitation before the Medical Association of the Greater City of New York, April 19, 1920.

you no doubt remember his descriptions of typical cases, and you have all had so many of them in your practice that I need not detail them again. I shall, therefore, mention states, disorders, or conditions that you may not have thought of as bound up in this subject, and in the instances recorded below they have occurred as recorded in a thousand case records. To me they have distinct significance. While the figures given below relate only to primary toxemias, the conditions occur quite as often in secondary toxemias.

In 619 cases of primary intestinal toxemia the conditions listed below were encountered in the following percentages:

Excessive fatigue	75
Anemia	73
Pernicious anemia	2
Anorexia	37
Insomnia	69
Skin condition (eczema, irritative rashes, recurring urticaria, acne)	9
Fatigue neuroses (neurasthenia)	67
Psychic disturbances	27
Recurring neuritis	7
Recurring headaches, backaches, etc.	69
Vagotonia	4
Dementia præcox	2
Eye symptoms (color blindness, spots in vision)	6
Asthma	3
Myocarditis (under fifty years)	7
Functional heart conditions	27
Chronic arthritis (nongouty or rheumatic) ..	5
Gastric hyperacidity	54
Gastric or intestinal atony	69
Gastric hyperesthesia	89
Ileal or colonic stasis	91
Chronic disease of the appendix	37
Megacecum (idiopathic)	11
Chronic colitis	69
Intestinal adhesions	32
Ptosis	52
Gallbladder conditions	12
Appendix disease	31
Abdominal distress (intestinal indigestion) ..	94
Endocrine disorders	61
Nephritis	9
Hypertrophic rhinitis	36
Loss of weight	51
Arteriosclerosis (under forty)	43
Functional hypertension	27
Functional hypotension	39

Even this array of disorders might not be so striking were it not for the fact that such marked improvement in many cases was met with while the patients were under treatment solely for the intestinal condition. While it is the consensus of opinion that in some of the cases no permanent benefit can be accomplished, the conditions were ameliorated markedly or cleared up entirely. When one has gone over the vast amount of work of this kind that I have in twelve years' time, the inevitable conclusion is that these conditions are a factor of importance in medicine, and I believe that no chronic condition is accurately judged, etiologically, unless the status of the intestinal canal is taken into consideration.

I have been asked to give a description of the methods of treatment I employ. This depends upon whether the case is primary or secondary, and since, in the primary case the accuracy of judging the bacterial change, the method of bacterial treatments and diets employed, the adherence of the patient

to treatment over four or five months' time, and other measures more difficult to control, only a few general points can be given. Almost daily I receive letters from colleagues, asking such questions as, "What vaccine do you use? What diet do you use?" This type of work is far from simple and is largely individualistic with the single case. Shifts from one vaccine to another, or one bacterial method to another, are common, and sometimes with ideal conditions no benefit or apparent results are brought about.

One might begin by expressing opinions of some of the methods that are employed in an aimless way, both by members of the profession and by the laity. Without careful investigation of the case, so-called colonic irrigations and instillations of bacteria into the rectum are being employed. Most of this effort is commercial in character and most unscientific. The intestinal canal was not intended for irrigation and while some immediate benefit may come from it, in the end it may do harm. No irrigations of the colon have ever been used by me. The general instillation of the *Bacillus bulgaricus* cultures or the *Bacillus acidophilus* by rectum or mouth is of no value. These organisms may accomplish certain results in a laboratory but do not in the human body. They never have acidified a neutral or alkaline intestinal tract, and in a case of acidity (saccharobutyric toxemia), they would do harm, if they could.

A year after the publication of my original article, Turck (2) suggested the use of the *Bacillus coli* subcutaneously. This was followed by Satterlee (3), both taking the stand that the *Bacillus coli* was inimical to the host and vaccination against its effect was helpful. Connellan (4) took Herter's and my own beliefs and assumed that the *Bacillus coli* was beneficial and that more should be added, using my rectal method but modifying it by counting the bacilli. Much criticism may be presented of the statements of these workers regarding my original method, most of which were unfair, unscientific, and proved that these workers had had little or no experience with the method I advocated, and were an effort, principally, to present an original treatment or method of their own. I draw your attention to Herter, Connellan, and myself who take the position that the colon bacilli should be increased in the host, and to Turck and Satterlee, who say that they should be decreased and immunity against them secured. The truth is that in certain types of cases either one of these is correct, but in all cases either one is more often wrong than right. More than that, however, to use one bacterium for the treatment of intestinal toxemia is like employing a single medication for everything in medicine, or one organism to treat all infections and expect their cure by the use of a single vaccine. There are many organisms and groups of them that are the causes of intestinal toxemia in man, and unless laboratory work is done to find out what the status of affairs is, this only adds to the unscientific work of men who see it only as a simple and single condition. In the writings of Turck, Satterlee and Connellan no reference is made to any laboratory procedure to prove the diagnosis in cer-

tain cases, and inasmuch as much investigation is possible of being carried out, even though it may be difficult and require experience and time, such work cannot be of permanent value even though some benefit may have resulted. More than that, to jump to conclusions from a clinical case to the use of a single organism as the cure of them all puts just opprobrium on it, for such hit or miss medicine makes for commercialism, and inhibits the attention and work of the best workers in medicine in a field that requires the closest and most careful study. This slipshod therapy is the cause of advertising and lay institutions engaging in it. There are places in this city run by lay people where patients wait in line for colonic irrigations and bacteria implantation at so much a visit.

There are no so-called intestinal antiseptics that are of any value, or any medical means that can change the biochemistry or bacteriology within the gut. The drinking of large quantities of water or fluid during the day (5) is of some value but not always advisable, difficult to keep up in quantities of 3450 c. c. per diem, and only of very moderate service in cases of putrefaction. Up to the present, fresh air, systematic exercise, temperate living, and an anticonstipation diet would accomplish more than any or all so far mentioned.

The two measures I would present as of the most value are diet and bacterial treatments. The diet should be a carbohydrate and hydrocarbon one in the putrefaction (indolic) case, a high protein in the fermentation (saccharobutyric) case, and one of carefully weighed foods so as to keep down to a minimum caloric value in the mixed form. Lactose by mouth is of no value, but the plan of Chetham-Strode and Benjafeld (6) of feeding coarse, uncrushed grains, somewhat sustains an acidity if a suitable bacteriology is present in the gut—which unfortunately is seldom met with in the putrefaction case; but when this is present a lactic acid carbon dioxide result can easily be accomplished. What one must always keep in mind, by dietetic treatment alone, is that most of the infecting forms of bacteria in the gut are facultative, and while they may be favorably influenced by diet, this is transitory and not dependable in therapy after a few weeks' time. Since no purgation should ever be permitted in these cases, the bowels must be regulated by the well known dietetic and physical measures, and not even by irrigations or enemata of any sort.

The bacterial treatments are based upon the findings in complete examinations of the stools and urine under known conditions of diet. This diet should be the normal one for the age, work, and weight of the individual. One suitable for a man weighing 150 pounds is the following:

Morning.—Two thin slices of well baked bread with butter liberally applied; one pint of oatmeal gruel, made of about forty grams or one and a half ounces of oatmeal; ten grams or one third ounce of butter; 200 grams or six and two thirds ounces of milk; 300 grams or ten ounces of water (all strained). One egg cooked in any form.

11 a. m.—Milk, half a pint or one glass.

Noon.—A good sized piece of roast beef or steak,

chopped or cut into very fine pieces (about 120 grams or four ounces) and served on a slice of toast; one bowl (about 250 grams or eight and a third ounces) of mashed potato, with twenty grams or two thirds of an ounce of butter.

4 p. m.—Milk, half a pint, one glass.

Night.—Same as for breakfast.

Water may be taken as desired.

After the third or fourth day a twenty-four hour collection of urine and a stool specimen passed in the same day are examined. In addition to the routine examination of the urine, the uric and oxalic acids are estimated, and a sulphate partition is made. The stool is examined in the usual way, and in addition a gram differential count of the gram negative and gram positive organisms and a study of the bacteria are made. Food detritus is separated from bacteria and an estimate of percentages in dried weights is made. When there is any doubt, inoculation observations under aerobic and anaerobic conditions and different media are performed. Complete x ray examination of the gastroenteric tract is done almost as a routine, the idea being to place the case in the secondary group if possible. Attention is also paid to stasis, ptosis and dilatation of different sections of the digestive tract in the abdomen. The detail in these examinations, differing as it does in different cases, is too large a matter to enter into here and may be found in the literature, but widely scattered. Suffice it to say that all of this work could be done by anyone who has had some practice in it, but it means work, and in my opinion the diagnosis of intestinal toxemia should be made in this way only and never just assumed from clinical aspects.

If bacterial treatments are carried out they should be autogenous if possible. It is not always easy to decide which one organism or what combination of organisms is infecting the canal. Symbioses rule high in intestinal bacteriology. Likewise it is not always possible to decide in advance whether the best results would come from the vaccination method, that of antagonisms or by biochemic alteration (using the infecting organisms but changing them biochemically by different media). Thus, with me the first three or four weeks are always experimental, with one week of laboratory observation. By close attention one gets straightened out. Both the rectal and subcutaneous routes are used, the bacteria being killed in the subcutaneous, but left viable in the rectal. A list of the bacterial treatments I have used in the three methods are the following:

RECTAL METHODS—BIOCHEMICAL ALTERATIONS.

Occasionally infecting bacteria can be changed biochemically by growing under different media and these used to substitute those present in the body. Successful examples of this have been found in cases of infections with *Bacillus coli aerogenes capsulatus*, *mesentericus* and *putrificus*.

RECTAL AND SUBCUTANEOUS METHODS—BACTERIAL ANTAGONISMS.

Saccharobutyric (high protein diet).

Bacillus aerogenes capsulatus.

Gram positive diplococci.

Gram positive single cocci.

Bacillus bifidus.

Bacillus coli (many different strains and perhaps collected from different sources). For the first two a strains, for the second two the b strains are best.

INDOLIC. (Low protein and high carbohydrate and hydrocarbon diet).

Bacillus coli.
Bacillus mesentericus.
 Gram negative streptococci.
 Gram negative staphylococci.
Bacillus proteus vulgaris (*Bacillus Welch*).
Bacillus cloaca (*Bacillus coli*, polyvalent strains).
Bacillus pyocyaneus (*Bacillus coli*, a strains).
Bacillus putrificus (*Bacillus coli*, b strains).
Bacillus acidophilus.
Bacillus bulgaricus.
Bacillus lactic aerogenes.

MIXED. (Least possible amounts of foods, no cheese, peeling of fruits—mostly boiled foods).

No action on antagonisms possible by rectal or subcutaneous methods excepting when a predominant type of bacteria is present.

The difference between the a and b strains of *Bacillus coli* is that a does not produce gas in saccharose, and the b does. The effects are the same on all the other sugars and on the coagulation of milk.

RECTAL AND SUBCUTANEOUS METHODS—VACCINE IMMUNITY.

Saccharobutyric.

Bacillus aerogenes capsulatus (rectal).
 Gram positive diplococci (skin, rarely; rectal, rarely).
 Gram positive single cocci (rectal).
Bacillus bifidus (rectal, rarely).
Bacillus putrificus (rectal, rarely).

INDOLIC.

Bacillus coli communis (rectal; skin).
Bacillus mesentericus (rectal).
Bacillus liquefaciens (rectal).
Bacillus proteus.
 Gram negative streptococci (skin).
 Staphylococci (skin).

MIXED.

Combination of methods outlined above according to predomination of fermentation or putrefaction and types of organism. The rectal method is used here altogether, and effort is made to get reactions and a leucocytosis of from ten to twenty thousand within eight hours after the injections.

The bacterial treatments are kept up for four or five months, according to the type of cases, method employed, and bacteria used. After the first month the diet is no longer important. Constructive and tonic additions to treatment are added, and at the end of the bacterial treatments the stools and urine are examined each month for six months to see that the results remain permanent.

These, briefly stated, are the methods I have employed for over ten years, the total number of cases now comprising close to five thousand. There may be easier and simpler forms of treatment but none that I know of gives the results that have been accomplished. To me the diagnosis and successful treatment of chronic excessive intestinal toxemia is far from a simple matter. The work should be done as dispassionately and as far from assumption as possible. In addition to the clinical aspects, the work should be done in both diagnosis and therapy almost entirely from the laboratory, and the closest sort of attention is required all the way through. I wish I knew of an easy way. The therapeutic part of the work may be done in a few moments of a patient's time in the office, but to conduct the bacterial treatments as I believe is required and treat thirty cases at a time requires that the laboratory must be actively working at least twelve hours

a day and often during the nights and on Sundays. To handle these cases properly requires more work with proportionately less financial remuneration for the expenditure of time, attention and energy, than any I know of in medicine. But the satisfaction experienced in the results obtained repays one, because commonly the results are so startling that one has hesitancy in recording them in the literature.

CONSTIPATION AND THE EFFECT OF PURGATIVES ON HEART AND VESSELS.

By OTTO LERCH, A. M., Ph. D., M. D.,
 New Orleans, La.

We speak of constipation when the bowels cannot be evacuated at least once a day without aid, that is, when a spontaneous emptying of the bowels has partly or entirely ceased and the patient has to take purgatives or enemas. Some patients use purgatives for years apparently without bad results, changing the remedies as they are recommended to them by relatives and friends, by the newspaper and by the druggist. However, a time will come when medicines lose their effect and the patient has to consult a physician. Long before this we find, in practice, a large number of people who suffer from incomplete constipation which usually precedes the complete form. These patients, still being able to procure an evacuation with purgatives or enemas, do not trouble about their ailment.

Constipation is a serious disease and should never be neglected when discovered during an examination or treated by adding another purgative to the list the patient has already used.

Health and comfort depend largely on well functioning bowels, and the diseases due to toxins absorbed from putrefying waste retained in the colon and from macroparasites and microparasites which find, under these conditions, a favorable soil in which to grow, are familiar to every practitioner. Sufficiency is the essential feature of a normal stool and though it is impossible to determine whether the stool corresponds in quantity to the food ingested, we can estimate, and occasionally by giving an enema after defecation can determine with some accuracy, whether the bowels have been emptied. A constipated stool is insufficient in quantity, hard, and delayed, though a semisolid and even liquid stool is constipated, if insufficient. A daily sufficient evacuation is the normal. Several factors are necessary to produce this.

1, A free, unobstructed intestinal canal; 2, a normal abdomen and normal muscles; 3, a sound and well functioning nervous system, causing in-

testinal peristalsis, relaxation of the sphincter and the action of the belly press, fixation of the diaphragm and pressure of the abdominal walls upon the abdominal contents; 4, a sufficient amount of waste matter in the colon; 5, a normal consistency of the fecal matter, neither too hard nor too soft.

Next of importance to the knowledge of the cause of the constipation is the diagnosis of the exact state when first seen; incomplete or complete, atonic or spastic. Constipation commences with atony of the bowels. In this state the muscles of the colon are weak and relaxed. This condition may last for years, till finally, due to irritation by hard scybala and abuse of purgatives, a catarrh is established. Hard scybala and flakes of mucus make the diagnosis of catarrh an easy matter. Flatulence and fine particles of mucus mixed with the fecal matter indicate an involvement of the small intestines, and icterus, that of the duodenum.

The constant irritation of the colon causes contractions; it feels like a smooth cylinder rolling under the palpating fingers, and it frequently gurgles. This manipulation is usually painful and the accompanying constipation may alternate with attacks of diarrhea and gradually pass into a continuous diarrhea. Membranous enteritis is an advanced state of catarrh. In this condition fecal matter is frequently retained for several days in the contracted parts of the colon, and the decomposed mucus acted upon by the acid stool is expelled in large flakes of cylindrical shape or like jelly, which under water take the form of membranes. The expelling of the mucus is accompanied by colic, after which the patient feels better.

CONDITIONS CAUSING INTESTINAL STASIS BY NARROWING AND OBSTRUCTING THE CANAL.

Among the conditions that will cause stasis are duodenal or rectal strictures, old scarified ulcers of tuberculosis and syphilis, malignant growths, partial torsion and moderate invagination, incomplete hernias, adhesions following peritonitis, appendicitis, cholecystitis and laparotomy, kinks, pressure of an ovarian cyst and gravid uterus, or an anal fissure, which due to pain will cause an excessive contraction of the sphincter. If the obstruction is located in the small intestines, stasis may be overlooked for a long while. The liquid contents of the small intestines pass the narrowed section for some time. These conditions have to be eliminated and a careful examination of the rectum, uterus, and hernial sites has to be made.

Inspection should never be neglected. Large saugelike stools indicate atony and ribbonlike stools spastic conditions or obstructions. Black stools are due to blood or medicaments like iron and bismuth. Calomel colors the stools green and grey fatty stools are due to absence of bile in diseases of gallbladder and duodenum, in severe anemias and chronic peritonitis. Fresh blood comes from the end of the tract. Black stools, if the coloring is due to blood, may be due to ulcers of stomach and duodenum, enteritis and malignant tumors, typhoid fever and purpura. Pus in large quantities indicates a rupture of an abdominal abscess into the intestines. If the pus is mixed with the stools, usually with blood, and accompanied by diarrhea, it indicates an ulceration of

the colon. Tenesmus, blood, and mucus are characteristic symptoms of dysentery. Mucus enveloping the stools indicates a catarrh of the rectum, and if mixed in small particles with the fecal matter, catarrh of the small bowels.

PATIENTS WITH ABNORMAL ABDOMENS.

Multipara with frequently ruptured perineums, and most enteroptotics, furnish the vast majority of constipated people. The enteroptotic usually has a pendulous abdomen with weak and relaxed abdominal walls. With some, however, the abdominal muscles may be hard, like cords, but more or less widely separated. The intestines are usually displaced and the transverse colon sometimes approaches the V shape which, of course, interferes with a normal evacuation. All of these patients are hysterical and neurasthenic and the influence of the nervous system is abnormal and adds to the trouble caused by the displacement and lack of muscular development.

TREATMENT OF CONSTIPATION.

This should be directed to the cause of the constipation and must be surgical in some cases. No cure can be hoped for unless the cause is treated. If the constipation is due to lack of enervation much can be done. Young girls and women do not respond to the call of nature on account of false modesty, and business men neglect it, because they are too busy. They commence to take purgatives and must take larger and larger doses to produce results and invariably end, often after many years, with serious difficulties.

It is not only necessary to strengthen and regulate the enervation in cases like these, in which the failure of the nervous system to act is the prime factor, but it is always useful, no matter what the cause may be. The bowels cannot be satisfactorily emptied unless the nervous system is intact and functioning properly. This is illustrated in organic diseases of the spine and brain as well as in toxemias. In these cases complete stasis or involuntary movements follow; a powerful peristaltic wave must pass down the intestinal tract, the sphincter must relax, the diaphragm must be fixed and the abdominal walls press upon their contents, when the brain is notified that the rectum is filled and evacuation needed. To have this act performed at a certain time and place, it must be learned until it is habitually performed. Infants are taught by their mothers till a fixed habit is established which usually lasts during life and is interrupted only by disease, change of place and later on by occupation and negligence. The taking of a journey on railroad or steamship interferes with it and people knowing this by experience provide themselves with purgatives before they enter on such a trip. Even moving into new quarters will often break the habit. The accustomed time and the familiar surroundings are necessary to produce prompt action. To re-establish the lost habit the patient must be advised to go to stool every morning at the same hour whether the desire is present or not and the importance of this measure must be explained to them and they must be impressed with it. Suggestion given by the physician or practised by the patient

himself will assist materially and often this alone is sufficient to cure. The inhibition which is present is removed by it and a powerful peristaltic wave will pass down the intestinal tract at a given time. To strengthen the habit and to make it firm it is best associated with another act habitually performed at the same time, or preceding it to give as it were a time signal to the brain. Most people have found out the efficiency of this measure by experience. They go to stool on arising, before or after the bath, before or after breakfast. Some have to smoke a cigar or pipe and some tell us that they cannot have an evacuation unless they take an apple at night, a soft boiled egg in the morning, a spoonful of honey and the like. Defecation is an automatic act and the habit must not be interfered with when it is once established.

CONSTIPATION DUE TO WEAKNESS OF MUSCLES.

It is evident that nerve stimulation cannot act efficiently if the muscular apparatus is not intact. The muscles of most patients suffering from constipation are weak and flabby, due to the lack of exercise. Bookkeepers, professional men, officials, sewing girls, tailors and all who lead a sedentary life are the victims. Massage and exercise may be used to strengthen the muscles. Before advising this, all inflammatory processes and conditions obstructing the intestinal canal must be excluded. If a tumor is palpable the intestines have to be cleansed thoroughly with enemas and castor oil and if after these measures the tumor can still be felt, massage must not be given. Even if a fecal tumor is diagnosed, massage is contraindicated, unless an inflammatory process can be excluded. Intestinal ulceration, tuberculosis, cancer, syphilis, chronic appendicitis, and cholecystitis, contraindicate massage.

Massage, when indicated, is commenced with a light circular stroke from right to left around the navel to treat the small intestines, to be followed by a firmer stroke along the colon. The masseur commences in the right iliac fossa, strokes along the ascending colon to the border of the ribs, across the abdomen, along the transverse colon and down the descending colon making deeper pressure on reaching the flexure and following it to the beginning of the rectum. This stroking has to be repeated a number of times to prepare for the rubbing. The left hand is then gently but deeply pressed into the iliac fossa with finger tips down, while the right hand rests over the left, the fingers of the left rub the ascending colon and gently but firmly push and press its contents onward along the course of the colon. This manipulation should be repeated a few times only; or the left hand is gradually deeply pressed into the right iliac fossa, next the right is placed before the left in the same manner, then the left before the right always gently pressing and pushing the colon contents onward. The rubbing and pushing have to be executed with a greater force along the flexure, the usual place where fecal matter collects. In some cases, especially in the obese and those with relaxed abdominal walls, the abdominal wall may be grasped with both hands and pushed from side to side, forward and backward, moving the whole of the abdominal contents.

Tapotement follows with the hand formed lightly to a fist or with the whole hand slightly made hollow so that only the borders strike. Vibration, best with an instrument (the vibrator), and finally a gentle circular effleurage from right to left close the procedure. If massage is given at all in the spastic form of constipation only a very gentle effleurage can be used and this with the greatest caution. A contracted colon will often relax under gentle treatment and pain may be stopped.

Abdominal massage should only be given by a physician who is familiar with the method or by a well trained masseur under the direction and observation of the physician. It is an efficient method and often will cure when all other methods have failed.

EXERCISE IN CONSTIPATION.

Outdoor life and exercise in the open are the best methods for preventing constipation and help to cure it when established. Walking, riding, rowing, tennis, golf, work in the garden, and other pleasurable exercises which divert the mind are the most useful. These patients are depressed and constantly occupied with their trouble which of course interferes with the evacuation. If these pleasurable exercises cannot be had or not in sufficient amount, then the patient has to be directed to walk to his place of business, the housewife has to go to market, etc. Room exercises are useful in every case. They are best taken in the morning naked before the bath, to secure an airbath. One of the most useful exercises is deep breathing. This strengthens the abdominal muscles and exerts a powerful pressure upon the abdominal contents. The patient lies on the floor on a blanket or upon a hard couch with knees flexed and mouth slightly opened. He then takes a deep breath, flattening the abdomen and exerting pressure upon its contents. He has to repeat this five times with a pause between each breath, a longer pause follows and the cycle of breathing has to be repeated five to six times. Bending forward, going into the bent knee position, picking up objects from the floor and similar exercises should be added.

HYDROTHERAPY.

Hydrotherapeutic measures are always helpful in the treatment of constipation. A warm bath in the morning, followed by a cold douche or ablution and friction with a rough towel, will be found helpful. In spastic constipation, warm and hot applications, a hot sitzbath or a full prolonged warm bath and hot drinks are indicated. Electricity is helpful, the sinusoidal current causing rhythmical contractions of the abdomen. The faradic current may be used instead, with a large electrode over the lumbar portion of the spine and a special electrode in the rectum. Before introducing the electrode, from 100 to 150 c. c. of lukewarm water should be injected to make contact between the mucous membranes of the rectum and the electrode. These various physiological measures act directly upon the intestines and improve general health by causing a better blood distribution, increase organ activity and free the blood from impurities. Muscles gain in strength and volume and the bowels commence to function.

DIET IN CONSTIPATION.

Bulk and consistency of the stools depend on the diet. A suitable diet has to be prescribed in every case. The exact state of the constipation, atonic or spastic, complete or incomplete, the state of the nutrition of the patient, whether fat or lean, age, sex, and occupation, indoor or outdoor life, the functioning of the endocrine glands, diseases which accompany the constipation, climate and season, all are factors which have to be carefully considered in prescribing the diet. The object of every diet is to furnish the needed amount of food for the production of energy and heat, for growth and repair. The diet must be sufficiently bulky and mechanically stimulating if the constipation is atonic, and non-irritating and stimulating chemically if it is spastic. Going to the toilet is best accomplished after breakfast, when the food of the preceding day has passed the intestinal tract and the morning meal excites it to act (Osborne). The seat of the toilet should be low or a footstool placed under the feet. The squatting position is assumed by primitive man to empty his bowels and is most efficient. People may know this from experience on hunting and fishing expeditions. In this position the thighs press well against the abdomen and the sphincter is stretched.

Fats and starches have to be increased or decreased according to the state of nutrition, occupation, climate and season, liquids regulated according to the consistency of the stool and meat allowed in proportion to the exercise taken. Meat is only assimilated during exercise and in disease.

In atonic constipation articles of food are to be preferred which excite and increase peristalsis and increase bulk; cold water in the morning, lemonade, buttermilk, cider and honey, fresh and stewed fruits like prunes, raisins, figs and dates, the dried fruits being soaked in water overnight and then well stewed; graham bread, and rye bread, the green vegetables like spinach, young sprouts, okra, snap beans, cauliflower and mustard greens, beet tops, carrots and potatoes; the coarser vegetables, cabbage, beans and peas, in selected cases. They produce flatulence and increase the trouble, if they do not cause an evacuation.

In spastic constipation fats, olive oil, butter and cream should be given in larger quantities; fruit sugar, honey, buttermilk and clabber, freshly pressed fruit juices, apple butter, plum butter, fruit jellies and purees of the tender green vegetables in butter act chemically and increase bulk without irritating the inflamed tract. All foods should be given in the semisolid state.

The following table may serve as a guide, varied as indications demand:

A glass of cold water should be taken on arising. Breakfast: A cup of coffee with cream; graham bread or rye bread with butter and honey; or clabber, buttermilk or cream cheese. Dinner: Lettuce and olive oil, creamed or baked potatoes with butter, the green vegetables in butter and fish or meat as indicated; ripe and juicy fruits, stewed fruits and fruit jellies. Supper: a glass of buttermilk, a plate of clabber, a soft boiled egg, graham bread, rye bread and butter. Fruit on going to bed.

ENEMAS.

Enemas are well adapted to empty the colon at once of stagnating masses of fecal matter. A large amount of water injected, to which soap, salt or castor oil has been added, stimulates the intestinal peristalsis powerfully, and an evacuation follows promptly. Solution of the stool is of little consideration. For mild stimulation a small enema of lukewarm water is sufficient. For stronger stimulation, the temperature of the water has to be cold, even ice cold, if a small enema is administered. If the higher portions of the colon are to be reached, the rectal tube has to be used (Nelaton). Oil enemas are of great importance and especially useful in the treatment of spastic constipation, though they do not act in every case. The oil may creep up to the ileum, it lessens absorption of water, acts as a lubricant and by splitting off oil acids stimulates peristalsis. Inflammatory processes and intestinal ulceration are not contraindications to the method. The enemas are best given at night and consist of a half to one pint of olive oil or cottonseed oil. The patient's hips are elevated and he lies on his right side. The colon tube, well covered with petrolatum is introduced about four to six inches and the oil allowed to flow into the colon under low pressure from fifteen to twenty minutes. The evacuation follows the next morning, though occasionally a watery enema may have to be added in the morning to produce results. A daily oil enema is rarely necessary. Enemas are useful and are the most harmless remedy, provided the technic is correct. Large enemas, too frequently repeated, distend the colon, which loses its tone, and this increases the trouble.

THE ENDOCRINE GLANDS.

It has been mentioned that the glands of internal secretion must be considered. Their function is disturbed in every disease and their failure to act may be the cause or the consequence of the constipation. If they are the cause, substitution and homostimulation alone will be frequently sufficient to relieve the condition (1). In either event medication in this direction is indicated. The obese if suffering from constipation due to poorly functioning thyroid and ovaries need the extract of these glands. However, the physiological methods must be combined with this medication to return the composition and distribution of the blood to the normal which in its turn will secure proper functioning of the failing glands. People finally have to get along with air, food, rest and exercise. The same may be said for the enteroptotics, with hypofunctioning of the pituitary, thyroid and adrenals. They need the substitute to get relief, and together with rest, diet, and the other therapeutic measures, to bring about a permanent cure. Rest in the recumbent posture secures a better blood supply to thyroid, thymus and pituitary and relieves the adrenals. Hormonal, a peristaltic hormone, is stored away in the spleen and has been successfully used to relieve chronic constipation, and biliary salts are now frequently employed for the same purpose. In the absence or diminution of bile, in hepatic disorders, bile and preparations containing it in some form, are indi-

cated, of which a number are on the market. Bile acts as a cholagogue and laxative, and neutralizes the intestinal ferment, mucinase, which coagulates mucus. Roger, who made this discovery, recommends oxgall in the treatment of membranous enteritis, and Pauchet recommends adrenal organotherapy.

THE TREATMENT OF CONSTIPATION WITH PURGATIVES.

With drugs we can meet every indication and empty a clogged bowel in short time. We can increase the tone of nerves and muscles, and increase or decrease peristalsis. We can influence the consistency of the stool by increasing or decreasing intestinal secretion, soften fecal matter, liquefy it or lubricate and increase the bulk.

The treatment with drugs is necessary in almost every case, though the physiological methods should be tried and drugs added and gradually withdrawn or the one and the other method alternately employed till a cure is perfected. If the constipation is not the main trouble but only a companion of some serious disease, purgatives are indicated. If we wish to act solely upon the nervous system, we give preparations of *nux vomica* or its alkaloid strychnine. It stimulates and gives tone to nerves and muscles. *Belladonna* and *atropine* retard peristalsis, relax spasms and stop pain, and are indicated in spastic condition of the intestines. If the stools are hard, drugs must be prescribed which increase intestinal secretion or strong solutions of the saline laxatives which liquefy the stools. *Liquid petrolatum* acts as a lubricant and the *agar-agar* preparations increase bulk, stimulating mechanically. Bran and similar irritating substances should not be used for any length of time and never in spastic constipation.

The vegetable purgatives are classified as aperients, laxatives and drastics. They act irritatingly upon the intestinal mucous membrane, increase peristalsis, produce hyperemia and increase secretions. The effect of their administration is a more or less thorough and rapid semisolid evacuation of the intestinal contents. Increased peristalsis and increased secretions prevent the thickening of the contents as they pass rapidly through the colon. Some of these, like *podophyllin*, *aloes*, and *senna*, act when given by hypodermic injection, but as they are excreted in the intestines it is probable that their action is a local reflex one, not differing from that when given by mouth. Most of these, especially the drastics, cause pain and inflammation when given in larger and repeated doses, due to the violent peristalsis they produce. Some have the reputation of increasing bile production and others do not act when bile is absent. Some increase the peristalsis of the whole intestinal tract and others affect the colon only. Those that act solely upon the colon are preferable in the treatment of chronic constipation where change of remedy and a prolonged use are necessary. Purgatives should be changed if a continuous use is indicated, to prevent intoxication, irritation of the mucous membrane and the taking of larger and larger doses, which becomes necessary if the same drug is continuously used. Drastics should be only occasionally used in cases without complications.

Castor oil and calomel are most frequently employed to empty the bowels thoroughly; they may be administered every eighth or tenth day. They affect the whole tract from pyloric orifice to rectum and empty the gallbladder by mechanical traction. The violent peristalsis opens the papilla. Croton oil is rarely used, and only in severe constipation without complications and in uremia when other means have failed. *Jalap* is frequently employed to produce watery stools in edema and ascites. *Podophyllin* acts as a cathartic in larger doses and may be used in small doses in the treatment of chronic constipation. It acts well in hepatic disorders. A common and very useful household remedy is a jam made of raisins, prunes, dates and figs, with a cup of honey or molasses to which *senna* is added. The active principles of *rhubarb*, *aloes*, *casgara sagrada* and others when given, are gradually set free in their passage through the intestines and exert their action especially in the colon. *Aloes* increases tone and irritability of the colon when given in doses of one twelfth to one grain, three times daily, sufficient to produce a satisfactory stool; the dose may be gradually decreased and finally discontinued. *Rhubarb* increases intestinal secretion and stimulates peristalsis. A small dose at night may be given for a long time without harm. *Casgara sagrada* acts upon muscles and tissues of the intestines through the sympathetic fibres which supply them. It acts well as a mild laxative, without causing pain or inconvenience. *Phenolphthalein* is effective and frequently used. *Black alder* is a tonic laxative especially useful for continuous employment when hemorrhoids are present.

The saline laxatives, magnesium sulphate and the sulphates, phosphates, tartrates and citrates of sodium and potassium attract water more than the cells of the body which property prevents absorption during their passage through the intestines, keep the intestinal contents in a liquid condition, and by slight local irritation increase peristalsis, which is aided by the hydrogen sulphide which is set free. The laxative mineral waters contain these salts and should be given warm an hour before breakfast.

The use of purgatives by rectum is rare; they do not produce a thorough evacuation but are useful when purgatives by mouth and enemas are contra-indicated; glycerine by injection or as a suppository are the most frequently used. Soap suppositories are useful in the treatment of infants.

PURGATIVES IN DISEASE.

Disturbed bowel action, frequently constipation, usually accompanies organic and infectious diseases. Prolonged rest, a change of diet and the intoxication produced by the disease itself, are the cause. It is next to impossible to treat constipation, accompanying disease, without purgatives, yet it is far more important to empty the bowels of the sick and keep them clean, than it is of healthy persons. The colon is an organ of absorption as well as a waste pipe. The epithelial cells covering the absorbing glands become paralyzed when exposed to putrefying waste too long, and allow toxins to pass which add to the toxins produced by disease. Normal function of all organs becomes seriously affected on account of in-

sufficient elimination by congested kidneys, impure blood and disturbed circulation; under such conditions recovery is difficult. "Blood alone cures, and to assist nature we have to purify it and bring it where it is needed. Nature repairs and cures with hyperemia. The purer the blood, the better the function of every organ, which in turn produces a perfect blood, hyperemia and recovery. It is therefore of the greatest importance to commence treatment by thoroughly emptying the bowels and keeping them clean with purgatives till recovery has progressed, then the physiological methods have to be substituted till the bowels function without aid." (2) Purgatives have to be prescribed according to the indications previously discussed. The acute infectious diseases commence usually with a chill, the skin is cold and clammy and the body temperature is high. There is no better way to correct the faulty circulation than by an enema, followed by a purgative, a hot footbath which brings the blood to the surface where it cools and returns cooled, and an icebag to the head to prevent congestion. The chill ceases, the body surface becomes warm and moist, the temperature drops, the high blood pressure is lowered and a dilated heart returns to the normal size and gains in strength, and with the clean bowels the patient has a better chance to recover. It is probable that it is this action of the purgatives on the circulation, which acts like bloodletting, together with their cleaning effect, which has led to the almost universal practice of commencing the treatment of the acute infectious diseases with a purgative and repeating the dose from time to time during its course. Whatever is done to relieve the patient, a permanent cure can only be secured when it is borne in mind that nature cures with hyperemia and that a pure blood—that is, a perfect composition of the blood—will assist her in her efforts. All therapeutic methods must be used to secure it. If we do this we assist nature and practice rational therapy.

DIETARY TREATMENT OF CONSTIPATION.

BY ROY UPHAM, M. D., F.A.C.S.,
Brooklyn, N. Y.

The part played by dietetics in the treatment of constipation, while most interesting, is, to my mind, subsidiary, and before preaching dogmatic statements on dietetics I shall present a brief consideration of the etiology of constipation, for if practical application of the dietetic treatment as outlined herein were attempted without an investigation of the etiological foundation of the condition, my statements would be considered inaccurate and be cast aside on the ground that they were not applicable to the practical work as seen daily in the office of the physician.

In discussing the dietetic principles it is necessary to keep clearly in mind that there are types of cases

in which dietetic principles are not to be applied until the etiological factor has been corrected.

Murray (1), in a clear and concise paper on the subject of constipation, takes as the keynote of his discussion the fact that an insufficient intake of water is the therapeutic factor in a large number of cases. We know that the daily excretion from the kidneys is forty-eight ounces; that sixteen ounces are excreted through the skin, and another sixteen ounces through respiration. Therefore, there must be a total of eighty ounces of fluid intake in order to supply nature's wants, and this is the first dietetic measure which must be insisted upon. Very few people make a practice of drinking water other than at their meal times, women being the worst offenders in this respect, and the records of my office show that there are three cases of constipation in women to one in men. I believe this is due to two faults: First, a lack of fluid intake, as previously stated; and, secondly, because of the fact that women are irregular in their habits, are prone to be late risers, and put off the act of defecation until the defecation reflex has become so benumbed that it no longer responds. It is an old adage that everybody's business is nobody's business, and it is applied in constipation that any old time to go results in no time for the desire to do so.

Therefore, in the treatment of constipation, we prescribe two glasses of very hot water on arising, to which is added, in some cases, a teaspoonful of salt, in others two teaspoonfuls of bicarbonate of soda, and in others two tablespoonfuls of milk sugar, the selection of the soda bicarbonate being made in the high acid cases and those accompanied with acidosis, and the milk sugar used in cases in which these factors are not present and for its distinctively laxative value. Following this we insist upon fifteen minutes' exercise, and then the patient, after a stimulating cold sponge, is dressed, feeling fit and ready for his breakfast, which should consist of some fruit, followed by a cereal, such as oatmeal or grape nuts, with which one or two tablespoonfuls of agar-agar are mixed. White bread should be interdicted in these cases for the reason that it does not cause sufficient intestinal stimulation; rye or Boston brown bread should be used in its place. Do not forget that butter is distinctly laxative, and the patient should be encouraged to take large amounts.

We have a special bread, the recipe for which we give to our patients, which is procurable at several bakeries in Brooklyn. The formula for this is as follows:

BRAN BREAD.

Two cups of wheat bran.
One cup of flour.
One teaspoonful of salt.
One and a half teaspoonfuls of baking powder.
Three tablespoonfuls of molasses.
Mix bran, flour, baking powder, salt, and molasses. Then add enough milk to make a dough. Various fruits, such as raisins, figs, and dates, may be added if desired. Bake the dough in the form of a loaf, or gems to vary the monotony. This same dough can also be steamed as a pudding and served with honey or other syrup.

We encourage our patients to take this bread in the morning with honey or marmalade, as both are

distinctly laxative. Bear in mind that smoked foods are distinctly stimulating to the bowels because of their chemical action, and for this reason, bacon, ham, and smoked fish are particularly advised. If the patient is allowed to take coffee, there is no better stimulant to intestinal motility than a cup of coffee, and patients are encouraged to use in this large quantities of condensed milk, as this is distinctly laxative.

Immediately after breakfast the patient is encouraged, if a male, to resort to a pipe of tobacco, and possibly a cigarette for women may do as well. This will stimulate a desire for movement, and the patient is told that time must be spent in the bathroom in an effort to produce a movement. Regularity is the keynote of success, and if a definite time of day is set, it should be directly after breakfast, because the intake of food on an empty stomach should stimulate gastrointestinal motility and bring on a desire for movement.

Neglecting the call of nature should never be allowed, as the rectum is a very delicate structure, and failure to respond is the cause of the majority of cases of constipation. A great aid is Kelly's suggestion of placing a box in front of the toilet seat so as to lift the feet from the floor, thereby bringing the thighs up to the trunk and aiding greatly in the expulsive force.

Patients are instructed at ten o'clock in the morning to drink a glass of buttermilk, sour milk, or koumiss, which, due to their chemical action, are a great stimulant to intestinal movement, and as many of these patients have a proteid type of intestinal intoxication, the lactic acid ferments in the fermented milk, while they may not fulfill all the claims that were made for them by Metchnikoff, do aid in the return of the intestinal putrefaction to a more normal type. They should be instructed to take eight ounces of water. Before luncheon four tablespoonfuls of olive oil are taken for its laxative action. If it is repulsive it can often be taken exceedingly cold or even on cracked ice, when it can be tolerated.

For luncheon the patient may have a small portion of meat, but there should be insistence upon a vegetable intake. Green beans, celery, cabbage, onion, cauliflower, carrots, and beets are particularly insisted upon, and with luncheon salad should be used with olive oil and vinegar.

The bread should be the same as for breakfast, and a dish of stewed fruits, figs, pickled peaches, or apricots taken with a glass of cider, which is distinctly laxative, with a tablespoonful of milk sugar in it. At four o'clock another glass of buttermilk is advised, and at five another glass of water. Dinner should be preceded by the olive oil and should consist of meat with vegetables, Brussels sprouts being thought of, a fruit salad with much oil and vinegar, and a dessert of stewed prunes, to which a tablespoonful of agar-agar has been added. Before retiring at night, if it does not disagree with the patient (by that I mean if it does not prevent his sleeping), some fruit should be taken along with some of the laxative bread, with honey on it. Carbonated waters are stimulants to peristalsis, and White Rock water can be advised. Ginger ale

should always be interdicted as it is distinctly constipating. Where the bowels are unusually sluggish, some time during the day a half cup of pure wheat bran taken with a glass of milk adds to the intestinal content.

The great point to be borne in mind in the treatment of cases of constipation is that these patients because of intestinal toxemia are constantly reducing the amount of their food until such time as there is not sufficient intake to stimulate the intestinal motility, and later on in this article a method will be presented showing how this can be overcome. The difficulty with this diet is that the patients become tired of certain articles, of food, and your success will be enhanced if you are able from time to time to offer suggestions which will vary the monotony.

Articles which will be particularly spoken of as laxatives are as follows: Many patients are aided by the use of the petroleum oil. This can be taken in doses of four tablespoonfuls three times a day. The difficulty in connection with the use of the oil is that often a patient loses control of the sphincter and the oil is passed when gas is expelled. To overcome this we have combined the oil with grape juice in the preparation of equal parts of grape juice and oil, which is emulsified by the use of mucilage of acacia in the proportion of one ounce of mucilage of acacia to the pint. If this is shaken up directly before taking it emulsifies the oil in a measure and prevents this disaster. By this method we have also been able to disguise the oil, and patients will take it to whom the plain oil would be repulsive. To a person who has no repugnance for oil, we often use plain white petrolatum, a teaspoonful three times a day. This is disguised by spreading it on a cracker and covering it with some jelly or marmalade. Honey has been referred to as being laxative, and molasses is also a most effective remedy. Patients are instructed to take two tablespoonfuls of molasses three or four times a day, which can be diluted with water and used as a beverage or, if the patient will take it, pure cider can be drunk freely.

There are numerous cereals and laxative biscuits of various kinds on the market, all of which are useful in the treatment of constipation. One of the most effective breakfast cereals is made of flaxseed and is easily procurable. Their action is along the same lines as agar-agar therapy. Wheat bran has already been spoken of and serves to supply the bulk but does not hold the moisture as agar-agar does. Our aim is to eliminate entirely the use of drugs with possibly the exception of various liver stimulants, such as oxgall, sodium succinate, and acid sodium oleate, which are effective through stimulation of the liver and not as direct laxatives or cathartics. The use of four to six ounces of oil injected into the rectum at night the last thing and held until morning is a most effective measure, particularly in the class of cases due to dyschezia of the rectal type of constipation.

There are certain articles of diet in which patients suffering from constipation should never indulge and among those which are particularly interdicted are puree soups, rice, sago, farina, cream of wheat, cheese, chocolate, cocoa, cranberries,

huckleberries, claret, and red wines; white wines may be used in moderation, if obtainable.

Of course, before going to bed the patient is instructed to exercise, using the abdominal exercises so familiar in the United States Army; or the shot bag principle of exercise. One important point to bear in mind in treating these patients is insistence upon their arising at the same time every day and taking their meals at the same time, thereby allowing the automatic functions to become once more regular in their activity. As has been hinted, extremes of temperature, either hot or cold, are extremely valuable as stimulants to bowel motility.

To the patient who has difficulty in consuming a sufficient amount of food we have found that the caloric method of feeding is applicable. By these lists the amount of food equal to 100 calories is readily determinable, and then the patient is instructed to eat a unit of calories a day, consuming 2,800 or 3,000 calories, and he is instructed to keep a list and to always eat the exact amount. If the patient does not gain weight by this method, or his general condition does not improve, by an increase of 200 calories in the daily intake at the end of each week an increasing amount of food can be forced upon him until a sufficient residue is left in the intestine to stimulate bowel movement.

To patients who are somewhat stubborn, the use of a rectal dilator inserted when they begin to dress in the morning and left in the rectum until a desire for bowel movement is induced is usually very effective. This is particularly so in cases of contracted spastic sphincters. Often a similar result can be obtained by the use of a gluten suppository; and often we have large suppositories made of cocoa butter which produce similar results.

In all work on dietetics at the present time we should not forget the part which the vitamins play. In the diet which has been outlined there is no lack of vitamins because of the fact that the diet is fairly well balanced and also because much raw food is consumed during the intake of the meal. Vitamins are readily supplied to the body in yeast, and we sometimes advise patients to eat half a cake of yeast three times a day, the yeast being stimulant in its nature to intestinal motility. Cabbage and potatoes are other splendid sources of vitamins (2).

In all cases of constipation the question of focal infection in any part of the body should not be forgotten and efforts made to eliminate any foci which may be present. We must also bear in mind that venous congestion incident to improper circulation in the intestine allows of abnormal invasion of the system by bacterial products and bacteria. Therefore, various electric modalities applied to the abdomen are extremely valuable in the way of stimulating the circulation and improving the general tone of the intestines. However, in the event of elaborate electrical apparatus not being at hand, the increased intake of food by a deposit of fat in the abdomen, aided by the increased vitality of the anterior abdominal wall, will produce a condition of increased intraabdominal pressure which will tend to return the circulation to normal.

To secure any success, every laxative measure

must be avoided, and often it must be insisted that the patient go for even forty-eight hours without a movement, at the end of which time a desire usually materializes, and from that time on, with a large bulky diet, frequently a normal condition of bowel movements results at once.

Grahams axioms (3) should be borne in mind. First, no case of chronic constipation is diagnosed or should be treated until a thorough proctological examination has been made. This consists not alone in the use of the proctoscope, but a digital examination should be made of every rectum, the whole secret of success in the treatment of the case being found at this time. There is an old adage that the difference between a gastrointestinal specialist and a general practitioner is the fact that the gastrointestinal specialist made a rectal examination; but with the advances which are constantly being made, we realize that more and more detail and care are being given to our patients, and the examination of the rectum is not overlooked as it has been in the past.

The previously outlined dietary principles are based upon broad phases, and failing in success, the diet has to be made typically applicable to various gastric and intestinal conditions, of which may be mentioned the type of stomach where no free hydrochloric acid is secreted with the attendant lack of activity of the enzymes, to the opposite state of affairs where pronounced hyperacidity is present; and let me mention the fact that in cases of gastric catarrh with diminished acidity a tendency of diarrheal conditions is prone to occur, whereas in constipation there is more likely to be hyperacidity. This will not follow in all cases, but we should realize that with the falling off in efficiency of gastric digestion there is a correspondingly deficient function of the liver and pancreas, and the absence of these two essential digestive factors in the intestine promote an undue fermentation, and, as a result, gastrogenic diarrhea occurs.

Another type of case which must be emphasized is that due to spasmodic colitis where there are abnormal spasmodic contractions, multiple in number, throughout the large intestine. This condition is usually accompanied by an increase in the production of mucus and gives rise to the condition which is known as mucous colitis. Formerly, the Austrian clinicians felt that this was an irritative condition and should be handled by an extremely bland diet, no irritative foods being given, and a diet similar to an ulcer diet being prescribed, hoping thereby that the points of irritation would disappear and that normal peristalsis would occur. After extensive experiments with the bland diet in constipation it has been practically discarded, and we attack this type of spasmodic colitis with the diet previously outlined.

These cases, as is true of many other cases of constipation, must be treated intelligently, and the patients should be informed that they may have a period of a few days of increased discomfort while their functions are becoming regulated, but that if they will have the courage to follow your instructions over a period of a few days normal results will ensue.

The only auxiliary measure allowed in these cases is a small enema in the morning after they have passed a day without a bowel movement, and the important factor is that this enema should be given at the time of normal bowel movement; that is, directly after breakfast. With this enema normal habits are usually established, and it is to be resorted to at infrequent intervals.

CONCLUSIONS.

1. Constipation is a preventable disease.
2. The pronounced causal factors are carelessness and laziness.
3. Plenty of water should be drunk to supply the necessities of the body.
4. There should be absolute regularity in the time of stool.
5. Dietetic principles should be applied with intelligence and the etiological causes thoroughly understood.
6. Cathartics will not cure constipation, but are positively sure to aggravate the condition.

CHOLEDOCHITIS, CHOLECYSTITIS AND CHOLELITHIASIS.*

The Need of Early Diagnosis and Treatment.

BY B. B. VINCENT LYON, M. D.,
Philadelphia,

Associate in Medicine, Jefferson Medical School; Chief of Clinic, Gastrointestinal Department, Jefferson Hospital, Philadelphia.

(Concluded from page 27)

DIAGNOSIS.

Diagnosis is then developed around the direct study of the bile and the manner of its discharge—the promptness with which A and B biles appear, the amount of B bile and the steadiness or the intermittency of its discharge, suggesting normal tonus, subtonus or hypertonus of gallbladder musculature and giving inferences as to its capacity; on the gross appearance of the several biles, color, consistency, viscosity, transparency, turbidity, flocculations, mucus, etc., and especially the careful examination into the cytology (epithelium, whether bile stained, its source, pus, leucocytes, crystals, concretions, red blood corpuscles, inflammatory debris, mucus, bacteria); into the chemistry (lecithin, cholesterin, calcium, pigments, effervescence on acidification); and into the bacteriology by culturation of each of the segregated samples of bile.

The bacteriological examination must be carefully conducted and promptly done to prevent streptococci and other less hardy organisms becoming overgrown with the more rapidly growing colon groups, *Bacillus pyocyaneus* and *Bacillus subtilis*. Cultures should be made at the time of the withdrawal of bile in the office, clinic or hospital, and planted in glucose broth flasks, blood agar tubes

and a third sample put in a sterile test tube, labeled and promptly sent to the pathologist or bacteriologist unless you are qualified to do the work yourself.

I have learned that I get more reliable cultures from planting the mucopurulent flakes, especially when heavily bile stained, which sink down to the bottom of the bottles, particularly those of B bile. These mucopurulent flakes, lifted out by a sterile pipette, are representative of material from the floor or walls of the gallbladder, ducts, or duodenum. Microscopically they show by far the most interesting and conclusive cytological condition. If more cultures were taken at operation from the gallbladder, from the mucopus from the floor of the gallbladder and not simply from the supernatant bile, I believe the average of positive cultures would be much higher, whether the gallbladder showed gross pathological changes or not. Withdrawing bile by a sterile hypodermic needle and syringe often gets the supernatant bile only. I wish to emphasize the need for careful cultural technic and prompt examination. Much important differential diagnosis hinges on this.

Again I would like to point out that it may be possible to decide where the source of the maximum infection may be, even though A and B, or A and B and C biles all deliver, say, streptococcus and colon bacillus, by taking advantage of colony counts. For instance, if you plant loopfuls of A and B biles and sow them through blood-agar petri plates and find that A bile grows seven colonies and B bile ninety-four, it is reasonable to conclude that the major source of the infection is the gallbladder and not the duct. Similarly, if the colony counts from C bile are far larger than A or B, the liver is to be suspected of being infected.

This plan is working out well and checking up well in differential diagnosis. I do not see now, however, how we can ascertain definitely whether or not the wall of the gallbladder or of the ducts, or the duodenal mucosa is definitely infected beyond the possibility of recovery by free drainage and topical treatment and sensitized vaccines. These direct diagnostic findings can, therefore, be used to amplify or to interpret the information secured from the history, the physical examination and from special examinations, such as the x ray, stool, stomach and blood.

We can thus hope progressively to modify in the future the one time true statement of Stockton (10): "It is difficult to reach a clinical knowledge as to the amount of bile that is being passed and as to the various constituents of the bile," and the statement of Smithies (11): "The average textbook considers cholecystitis in a vague uncertain way, as though it were not an ailment second in frequency to all intraabdominal disease only to lesions of the appendix. Commonly cholelithiasis meets recognition as an acute dramatic, abdominal crisis, in which the chief rôles are played by colic, chills, fever, sweats, and jaundice."

The differential diagnosis between cholelithiasis and cholecystitis depends to a large extent on the bacteriology and cytology plus the gross normality or abnormality of the bile. This will be referred

*Read before the Twenty-Third Annual Meeting of the American Gastroenterological Society, May 3 and 4, 1920.

to in greater detail when the diagnosis of atony of the gallbladder is discussed. Of course, if the gallbladder has previously been removed the problem is easier. Empyema of the gallbladder is easiest to diagnose directly, provided the gallbladder is mechanically able to discharge a specimen of its contents. Dr. Brown, of Montana, recently told me that he had examined some seventy or more suspected gallbladder cases by this method. Among them were four cases of empyema successfully and directly diagnosed and two of the four he had successfully drained and tided over acute complications that did not warrant the risk of surgery at the time.

CHOLELITHIASIS.

Regarding the diagnosis of cholelithiasis, some helpful points can now be suggested. Of course, the recovery of gallstones themselves is the *sine qua non* of this diagnosis. I have recovered small concretions through the duodenal tube in one instance, and on several other occasions have made stones pass either out of the gallbladder or out of the duct, stones too large to be recovered by tube but found on sieving the stools. In none of these cases, however, do I feel that this would have happened at the time of diagnostic drainage if magnesium sulphate introduced locally did not possess the power to relax the sphincter and to contract the gallbladder wall. Why it loses much of its power to do so if first passed across the gastric mucosa, as Meltzer first noted and which I have confirmed, I cannot explain, but such apparently is the case.

Next in importance to direct recovery of definite gallstones, gallsand and the sense of grittiness to the finger suggest the calculus forming possibility. So does the microscopic finding of large agminated masses of precipitated crystals of bile salts or pigments, since it suggests that the liver cell has lost the power to hold these substances in solution, as occurs in the formation of liver or hepatic duct stones, or that the bile in the gallbladder has become so static that excessive concentration and crystallization has taken place. I have previously shown that the sudden dense turbidity that one sees taking place in an otherwise perfectly transparent bile during a drainage is due to a sudden spurt of acid gastric juice entering the duodenum and mixing with the bile. This was confusing at first and is still annoying. Dr. Bartle, working with me, found that this turbidity could be artificially produced in the case of every clear bile by artificially adding dilute hydrochloric acid. The turbidity varies according to the strength of the acid and the chemical constituents of the bile. Later certain clear biles were encountered in which an effervescence as well as the turbidity was produced on adding hydrochloric acid, similar to the reaction of acetic acid and calcium carbonates in the urine, and the question has been suggested as to whether this might mean the possibility of potential or formed calcium carbonate stones in the gallbladder. More work must be done on this point.

ATONY OF THE GALLBLADDER.

Relative atony of the gallbladder is something I believe we can diagnose and which I consider to be

of extreme importance because I believe it to be one of the earlier phases of gallbladder disease and the forerunner of gallstones and of gallbladder infections. This diagnosis is suggested in three ways:

1. The recovery of static or off color bile, ranging from the deeper shades of golden yellow, into the green yellows, green blacks, and blacks, and possessing an increasing viscosity from that of a thick syrup to that of tar. Where the viscosity is heavy and the cytology shows much mucus and desquamating masses of bile stained, high columnar epithelium, and quantities of precipitated crystals, I consider this an atonic catarrhal cholecystitis and a potential forerunner of calculi. I have seen this type alone as well as the type of infected cholecystitis with a swarming bacterial flora and pus, blood and inflammatory debris. This is the outspoken type giving rise to well marked clinical symptoms. But I have also frequently seen the masked infective cholecystitis with swarming bacteria and static bile, but no cytological inflammatory reaction or marked cellular destruction. These are the cases that are early, do not show interpretable clinical symptoms, but give rise to the vague atypical dyspepsias, and these too are the cases which operatively are passed over as grossly normal and in which the appendix is removed and the masked focus left to breed pathological conditions.

2. In the amount of static bile recovered. If a gallbladder's normal capacity may be considered two and a half ounces, and if four ounces of this type of bile can be recovered in bottles, it seems reasonable to assume that the gallbladder in question must be functionally atonic and unable to move its contents promptly or the cystic or common ducts must be partially obstructed. If six to twelve or more ounces of this static bile is recoverable (as in my series of cases), it must appear that the normal distensible sac has been overdistended, has become dilated and has perhaps ruptured some of its muscle fibres and may be progressing to an absolute atony. The functional type of relative atony seems to fit in well with many of the cases presenting symptoms of so-called biliousness and of cyclic migraine attacks. These also are groups that may be the forerunners of gallstones and pathological gallbladder conditions.

3. In normal cases when B bile is recovered it comes continuously until replaced by the appearance of C bile and averages from one to three ounces and further stimulation with magnesium sulphate fails to recover any more. Whereas, where atony is suspected, B bile appears, the bile is static to varying degrees but gallbladder discharge may be intermittent, that is, two or three ounces of B bile and then ten to thirty c. c. of C bile and again two, three or four more ounces of static B bile. Furthermore it is possible to deliver more of this type of bile on restimulating with magnesium sulphate. It is reasonable to suppose that such gallbladder musculatures are deficient in tone and incapable of emptying completely, as in atony of the urinary bladder, with its residual urine. Of course, there are limits to the amounts of magnesium sulphate that should be used. I think a safe

limit might be placed at ninety c. c. of thirty-three per cent. representing thirty c. c. of the saturated solution. My custom is to start with seventy-five c. c. and note how much I recover in the first bottle unmixed with bile. If I recover, say forty c. c. I can then restimulate to the amount of fifty-five c. c. additional and still keep with the limit of ninety c. c.

It may be as well to mention here the fact that in many of these cases we are draining highly infected material from the biliary passages and that some of this fails to be aspirated into the bottles and passes down the intestines possibly to infect susceptible zones lower down. There are two logical ways to overcome this. First, by douching the duodenum with various disinfecting solutions, potassium permanganate, silver nitrate or possibly chloramine-T, and get back what one can. I personally do this, but do not advocate it for any one beginning duodenal work of this kind, for it has an element of risk, because it is by no means certain that you can get out again what you put in. Secondly, to hurry along the infective material as rapidly as possible through the intestines. To do this I always follow each biliary drainage, whether for diagnosis or treatment, with a duodenal enema. I prefer Ringer's solution, for its healing qualities, reinforced by a five tenths per cent. or twenty-five hundredths per cent. sodium sulphate depending upon how much magnesium sulphate solution has failed to be recovered. The total amount of the duodenal enema I keep at 250 c. c., introduced at 105° and require at least twenty minutes for its introduction. This is usually effective in producing a large fluid or semifluid bowel movement in from fifteen to ninety minutes. Furthermore, no patient leaves my office without being given a cup of bouillon and some crackers. This tides them over the faintness of hunger and free intestinal evacuation.

I wish to refer now to the diagnostic inferences that might be possible in the failure to obtain B or gallbladder bile. They are so obvious that they merely need tabulation.

It might indicate any of these possibilities: 1. Obstruction of cystic duct, by a, stone or stones, b, adhesions or angulations or stricture, c, pressure from without, tumors, lymphatic glands, or, d, inspissated mucus, hydrops. 2. Gallbladder contents, may be entirely calculi and no, or relatively little, bile. 3. Weakness of gallbladder musculature, atony, dilatation, too weak to move its fluid contents. 4. Tarry bile, ultrastatic, too thick to flow. 5. Fibrosis of the gallbladder.

TREATMENT.

This method during the past three years has been successfully used in the treatment of all of the states of biliary diseases mentioned in the following paragraphs. Three years is too short a time to predicate an opinion as to the ultimate possibilities this method of nonsurgical biliary drainage may possess. Its principles are soundly established and are logical. Furthermore, one is able to gauge progress made by the improvement in direct objective findings in addition to the usual method of estimating clinical and symptomatic improve-

ment. The ultimate criterion of a cure in the real sense is more nearly within our grasp.

We are mechanically applying the surgical principles of free drainage for infected sacs, tubes and tissues, of free drainage for catarrhal states of inflammation of various grades but without infection, of free drainage for gallbladders that are atonic and contain static bile in which sooner or later there develop stones or a more serious pathological condition, and while applying surgical principles we are doing it nonsurgically and avoiding certain surgical risks. Besides this, and even more important, we are preserving tissue which may possess a power of recovery of function beyond our present conception. Patients suitable for this method of treatment should be selected. Its real sphere of usefulness lies in giving a direct method of treatment in early stages of disease, diagnosed early, before gross pathological changes have taken place. Removal of pathological tissue, of gallstones, etc., must be left to the surgeon. Our aim should be to learn better to diagnose the beginnings of these diseases and to institute promptly direct, rational and safe measures of treatment. We may legitimately hope that this method, if intelligently applied, may decrease the number of cases requiring serious and dangerous surgery.

TECHNIC.

The technic of treatment is not difficult and can be carried out by hospital interns and even by nurses after a little practice. It does not require the expert supervision of the highly trained specialist, although it is naturally better if such service can be secured. Here it differs at once from the necessity of procuring the most skillful surgeon for surgery of the upper right quadrant of the abdomen. This is not the field for the occasional operator. It is time that we recast some of our accepted views. To operate and have the patient live and to operate and make the patient well are two very different things. It is one thing to cut out pathological tissue and quite another to restore pathological physiology already existent, or that created or increased by the operative procedure.

The technic of this treatment is easy but it is the skill in the general diagnosis and the technic of handling the minutiae of special diagnosis that require the highly trained specialist, and the better his training in pathology and physiology and the keener his enthusiasm for the use of the microscope, the test and culture tube the more valuable will be his opinion.

Simple catharrhal jaundice may be treated very satisfactorily by this method. The duration of jaundice in the ordinary case may be cut in half and potential drainage to the ducts, gallbladder and liver may be prevented. Recent papers (12) have shown what can be done in the treatment of this condition by this method.

Cholelithiasis and cholangitis may be successfully treated in favorable cases, especially where there has not been any surgical interference. That means the relatively early cases. Even in late cases where there has been well established pathology and several preceding operations this method may give an un-

expected brilliant result. This was evidenced in one young girl whose case I have reported at length (8). She had three major and one minor gallbladder and duct operations performed in three years with two further years of constant suffering and remittent exacerbations of choledochitis, finally culminating in a very severe and acute attack, with complete duct obstruction, chills, fever, sweats, high leucocytosis and toxemia, yet her condition, with its very serious aspects, responded splendidly to this method of attack, and today the girl is well and has remained free from any further exacerbation for nearly three years.

I have within the week seen a young woman of twenty-six who had her gallbladder and stones removed twenty-three months ago; she had two weeks of surgical tube drainage and nearly four months of dressing drainage. She remained free from symptoms for just two months, when exacerbations recurred and during the past eighteen months she had had an equal number of attacks of severe colicky pain which two weeks ago culminated in chills, fever, and acute obstructive jaundice. Unless her common duct can be speedily unplugged dilatation of the ducts and biliary cirrhosis may develop because her safety valve, the gallbladder, has been removed. It is more difficult to unplug such a duct when the gallbladder has been removed, because the contraction of the bladder supplies a good part of the *vis á tergo*. It is remarkable to what extent the gallbladder can distend, as witness the case of the little girl at Johns Hopkins Hospital, recently reported upon, whose very distended gallbladder contained nearly a litre of bile.

What I have said of choledochitis applies to cholecystitis, perhaps if anything more favorably. Especially so in the early cases, such as those complicating typhoid fever, and masked focal infections of the gallbladder. This is the time to diagnose and to drain, nonsurgically, in such cases and not wait for the development of a full blown pathological condition.

Empyema of the gallbladder has been successfully treated during its acute phases in patients who presented severe cardiorenal contraindications for surgery. That is to say, their gallbladders have been drained successfully, the maximum source of their toxemia has been temporarily removed, and they have been tided over to a point where corrective surgery for the removal of the pathological condition could be more safely practised. There is nothing to prevent the success of nonsurgical drainage in empyema provided the cystic duct is patulous. This is by no means recommended as the method of choice but as a possible alternative measure worthy of trial in selected cases presenting grave surgical contraindications.

Cholelithiasis remains entirely beyond the scope of this method, although stones have been made to pass through the common duct. Our efforts should be directed to the detection and treatment of the early states of pathological physiology and to the prevention of calculi. The method has, however, distinct merit as a postoperative follow up treatment to prevent the reformation of stones and to continue to drain, *ex corpore*, still

infected bile beyond the limits afforded by surgical methods of drainage. This has been proved a successful measure.

The one field where this method can be strongly recommended is in the treatment of biliary stasis or faulty retention of gallbladder bile. If more cases of biliousness were investigated by this method it would surprise many of you to find the gallbladder atonic to varying degrees and unable to discharge its static bile. These are the patients in whom, if they are left to themselves and their cholagogues, a quarry of stones will develop. These patients do extremely well and it is remarkable to see their improvement in color, digestion and bowel function. They lose their lethargy and recover their sense of wellbeing. Many of these atonic gallbladders are harboring pathogenic microorganisms but still preserve sufficient mucosal resistance to prevent infection of their walls. This is the time to treat them energetically by frequent drainage. Bacterial identification should be carefully made and autogenous vaccines have an important place of usefulness. It is very important to search back for primary foci of matched bacteriology in the teeth, tonsils, sinuses, bronchial tract, stomach or duodenum and remove them. Many of these cases of biliary stasis are associated with various forms of migraine. Some of them respond almost miraculously to biliary drainage; others are very resistant, suggesting a different causative factor.

SUMMARY.

To sum up in a few words, this method has already achieved a position of importance in the diagnosis of biliary diseases. In the field of treatment it is certainly the method of choice for biliary stasis, gallbladder atony, and in the early states of catarrh and infection. It may be found to decrease the incidence of stone formation and thus of cancer of the gallbladder. It will decrease the tendency to damage the pancreas and liver. It may decrease the frequency of acute and chronic pancreatitis, of biliary cirrhosis and possibly diabetes. It may have a place as an alternative method of treatment for some of the surgical groups presenting operative contraindication. It certainly is useful as a post-surgical followup plan of treatment in many cases.

More time must elapse to prove its final evaluation. Quite true, but one must start somewhere. It has had a good beginning. It may go further. It is within my province to call your attention to it, and within yours to prove that it has the merit which I believe it to possess.

As to future possibilities, it offers an attractive opportunity for further direct clinical investigation into and the interpretation of: 1. What are the cholagogues? How do they act? a. By increasing liver secretion of bile or the velocity of its discharge? b. Do they empty the gallbladder? 2. Precursory states and phases of gallstones and infections, i. e. biliary stasis and atony. 3. Parallel studies on pancreatic secretion, velocity of elaboration of ferments and their discharge. What are the elective pancreatic secretagogues? Have they a place in the prevention and treatment of diabetes? 4. Extending the scope of chemical investigations into the composition and physical properties of bile.

Here are many usefully important problems awaiting solution.

PEPTIC ULCER.

Clinically and Röntgenologically Considered.

BY JOSEPH S. DIAMOND, M. D.,

NEW YORK,

Associate Röntgenologist, Beth Israel Hospital.

The refinements in diagnosis of peptic ulcer have not only facilitated the detection of this intractable disease, but have broadened our views and clarified our understanding of the varied pathological manifestations. The functional gastric neurosis to which our older textbooks devote chapters are today seen in a different light, and many of them can presently be interpreted on pathological bases. The so-called Reichman disease, spoken of as a functional hypersecretion, is today better understood as hypersecretion concomitant with duodenal ulcer. Hyperacidity is no longer regarded as simple or functional hyperchlorhydria, but can invariably be accounted for, and if not resulting from gastric disease, perhaps arises reflexly from a lesion of a remote abdominal organ. Such able workers as Mayo, Smithies, Einhorn, Hamburger, Case, Cole, and others in this country; and Moynihan, Forsel, Hau-deck, Holz-knecht, Rieder, and Retzius abroad, have enriched the literature, each adding something to pathogenesis, diagnosis, or treatment.

The symptomatology of ulcer has been considerably popularized at present, so much so that every physician is on his guard when confronted with a symptom complex of gastric complaints. Moynihan has said that a diagnosis of duodenal ulcer can be made by correspondence. While a case presenting classic symptoms may be recognized with ease, yet it is only by careful analytical study embracing the subject broadly that conclusions approach correct diagnosis can be reached. The borderline cases are still in a maze of complexity, and create many doubts, especially so when the conscientious surgeon is confronted with exploratory laparotomies in these obscure cases.

An attempt will be made in this article to cover briefly the most important data at present utilized in the diagnosis of peptic ulcer and to discuss their

merits, as well as the modern conception of etiology, pathology, symptomatology, and disturbed motor and secretory functions. There are three main factors to be considered. Enumerated in the order of their importance, they may be cited as follows: 1, anamnesis, or the clinical symptom complex; 2, röntgen examination; 3, chemistry of the stomach and intestines.

ETIOLOGY AND PATHOLOGICAL ANATOMY.

The etiology of peptic ulcer still forms a fascinating chapter in medical literature and though shy of complete solution, yet it is nearer the comprehensive goal. Many theories have been advanced and while there is truth in some, in others considerable contradiction outweighs the assertions. The modern conception of pathogenesis of peptic ulcer includes several factors which may be cited as follows: 1, spasm or neurogenesis; 2, infection, and 3, traumatism, whether mechanical, physical or chemical.

While the literature abounds in numerous data of experimental research work beginning with Virchow in 1885, most of these have but a historical interest. Virchow's theory of embolism or thrombosis causing circulatory interference in localized areas in the stomach wall, thus causing necrosis, ulceration and digestion, did not stand the scrutiny of later studies. The gastric vessels are not terminal and are rich in anastomosis. Furthermore, the age affected by ulcer is not one conducive to vascular changes. Even those ulcers, produced by Cohnheim and later by McCallum by the injection of finely divided suspension of lead chromate or ultramarine blue causing hemorrhagic ulcerations in the mucous membranes, apparently on the theory of circulatory interference, heal promptly like all other traumatic ulcers without the production of the typical round ulcer. Other experiments, such as obstructing the portal circulation, severing the vagi, or cutting various segments of the cord at various levels, have neither produced the so-called peptic ulcer nor have been conducive to any logical understanding as to the causation of this type of ulcer.

The problem that confronts us is to understand what particular pathological process takes place which leads to the formation of the typical round, punched out ulcer, with sloughing base and overhanging edges, the so-called classic peptic ulcer, the ulcer that is chronic and occurs at stated intervals. It must possess all these characteristics before it can be classed as peptic ulcer. It is well known that chemical ulcers, as well as other traumatic ulcers, do occur but heal rapidly without giving any of these recognized manifestations. Such cannot be regarded as peptic ulcer. As we shall see later on, there is another factor to be considered which tends to embrace such morbid processes.

Spasm.—The theory of spasm of the gastric muscles as a forerunner of ulcer has been mentioned by Talma and his pupil Von Yzeren. Strong evidence has been accumulated in recent years that place spasm as the most plausible factor in the causation of gastric ulcer. Eppinger and Hess, through their elaborate studies of the autonomic or vegetative nervous system and the disturbances attending vago-

tonia and sympathicotonia, have shown a close analogy between the symptom complex of ulcer and the many similar manifestations of the vagotonic state. They call attention to the local vagotonia where the various stimuli act upon the autonomic supply to the smooth muscle and secretory apparatus of the stomach and produce pathological states of the same nature as are found when the autonomic system is in an increased state of irritability. These are analogous to the subjective as well as many objective manifestations of gastric ulcer. In truth do we not observe clinically the symptom of pyrosis, sour eructations, fullness and pressure after meals, hunger pain in both conclusions? Do we not see under the fluoroscope the same hyperkinetic manifestations of deep peristaltic waves, gastrospasm with incisures, pylorospasm, and cardiospasm? Do we not find the same chemical changes of high acidity in both? And furthermore, are not the susceptibilities of the inherent biological properties, their reaction to chemical substances (atropine, pilocarpine) alike in both states?

Gross and Held point out the muscular distribution in the structure of the stomach emphasizing that the strongest musculature is where function is greatest and where spasm most abounds. The groove of Retzius is strengthened by the oblique bundle of fibres. The antrum and pylorus as well have the greatest muscular supply. It is in these regions that ulcer most frequently occurs.

Friedman and Hamburger produced acute ulcers in a series of experiments in dogs by the injection of five per cent. silver nitrate into the submucous tissue of the stomach. They succeeded in retarding the healing of these ulcers by ligation of the pylorus and thereby rendering them chronic. They deduce from their experiments that the delay in healing is greater when the food and gastric juice are ground against the ulcer with unusual violence. They conclude further that any acute ulcer in man which may be produced by abrasion of a coarse food particle or other form of traumatism will become a chronic ulcer when there is an associated condition of spasm. When we remember that pylorospasm results from an increased irritability of the autonomic nerve supply, or from reflexes of distal organs, supplied by the same nerves, the gallbladder, appendix, cecum, proximal colon, liver, and pancreas, it is easy to conceive how an abrasion in the mucous membrane of the stomach may become a chronic ulcer. Pylorospasm is usually associated with hyperacidity, hyperperistalsis, and impaired motility, and these are the factors that are the forerunners of and prepare the field for, the development of gastric ulcer.

Infection.—Rosenow states that the intravenous injection of streptococci of the proper grade of virulence (moderately high grade) may be followed by ulcer of the stomach and duodenum. The culture obtained was usually from infected tonsils in cases of articular rheumatism or from the base of an indurated chronic ulcer in man. These various strains, when passed a number of times through various animals until the proper virulence was obtained, sometimes produced ulcer after the fifteenth injection. All these ulcers appear very acute and show

evidences of a severe grade of infection by the inflammatory reaction, hemorrhages and rapid sloughing of tissue—often causing perforation. Simultaneously with these ulcers are found acute arthritis, myositis, nephritis and other evidences of a septic general infection.

From the foregoing paragraph one must conclude that the analogy between those septic conditions and peptic ulcers in man is still very remote. The link in the chain from this type of experiments has as yet not established the relation between infection and peptic ulcer.

John B. Deaver perhaps best sums up the infection theory, as follows: "The action of bacteria on the capillaries of the stomach causes an irritation and injury to the endothelial cells with an escape of blood into the submucous space. This later forms a localized abscess which discharges and leaves an ulcer base. The constant bathing in an acid medium tends to keep the ulcer chronic."

Traumatism.—Many have thought that traumatism in all forms, whether physical, mechanical, or chemical, can produce ulcers. Violence, such as that produced by repeated blows over the abdomen, has been said to produce ulcer. Tight lacing and occupations requiring constant pressure over the upper abdomen have been attributed as a cause of ulcer. Leube and Decker have shown that burning the mucosa of the stomach with hot food caused ulcer. W. J. Mayo states that the ingestion of hot liquid foods will cause ulcer. Such theories, while very plausible, can only be held accountable for ulcers on a limited area on or about the groove of Retzius close to the incisura cardica and down as far as the pars media. The temperature of the food is surely lowered by the time it reaches the pylorus on mixing with the secretions of the stomach and the chyme. When we further consider that seventy-eight per cent. of all the peptic ulcers are contained in the duodenum within the postpyloric regions, surely this form of trauma cannot be held responsible for the large field of peptic ulcers.

Hyperacidity and autodigestion.—Attention has been drawn to the fact that peptic ulcer is found only in that portion of the digestive tract where the presence of hydrochloric acid is found. A great deal of importance has been attached to the hyperacid gastric juice. Pavy, Samuelson, and Matthews have retarded the healing of ulcer by irrigating the stomach of a dog with a 0.56 per cent. solution of hydrochloric acid. The action thus produced would be a corrosion of the superficial layers of tissue immediately followed by the digestive act of pepsin in the acid media. The question as to why the stomach does not digest itself in toto has been answered by Weinland who attempted to prove the presence of a living antiferment in the living cells of the stomach thus protecting the ferment action of pepsin. Weinland thinks that the inability of a localized area of tissue to produce antipepsin in a hyperacid medium causes local digestion and ulcer formation.

From this exposition of the etiology of peptic ulcer we must conclude that there is always present a predisposing factor consisting of an increased irritability of the autonomic nervous system. This state is a forerunner and acts as a receptive back-

ground. The inciting factor may be an abrasion in the mucous membrane which is produced either by a coarse food particle or any other mechanical, thermal, bacterial or chemical agent. When such superficial abrasion occurs under these favorable circumstances when bathed by the hyperacid and pepsin medium, when subjected to the constant grinding of the hyperirritable gastric musculature, and where pylorospasm and gastrospasm are constant factors, only under such states is it plausible to assume that a peptic ulcer with all its characteristics, may develop.

CLINICAL MANIFESTATIONS OR ANAMNESIS.

Moynihan says: "First and foremost (indeed if not exclusively) the anamnesis. Great importance must be attributed to a good clinical history. One should learn to acquire the art of elucidating the important symptoms of the patient's complaint. Patients often dwell on the least significant of the symptom complex and will mention subjective symptoms that have no bearing on their chief complaint." A great teacher, T. C. Janeway, often said: "Regard your patient as a witness; cross examine him as a lawyer would. The greater the art of your cross examination the more facts will you be able to gather from your patient." The type of patient, whether hypersensitive or phlegmatic as well as the degree of intellect, should be taken into consideration. His ability in interpreting and imparting his own complaints to the examining physician must likewise be considered.

The characteristic symptom, whose presence we must aim to ascertain, is pain. There must be pain in ulcer. Without pain there can be no ulcer. The pain is most often described as gnawing, boring, or burning. The pains are usually so spoken of at the highest stage of their severity. In the earlier stages the pain may not be so characteristic. A history can be obtained of an insidious onset, of a sense of distention or oppression, of fullness or weight in the epigastrium after meals. Associated with these, other symptoms make their appearance, such as pyrosis, eructation and waterbrash whose acrid taste often burn the throat. During this stage some will still pay little or no attention to these symptoms; others will seek relief in bicarbonate of soda which stops the discomfort by the expulsion of gas and neutralization of the acid. A sensation of choking in the throat which is often regarded as a neurosis manifests itself, which is none other than an indication of vagotonia concomitant with the general increase in the irritability of the autonomic nervous system occurring in ulcer. The periodicity of these symptoms, their seasonal appearance and disappearance, is rather striking. Patients will often say that they feel better during summer and are worse during early spring or late fall.

As the disease progresses intense pain makes its appearance, coming always at a definite interval after a meal and may be accompanied by the distress of distention or a 'blown-out' feeling. At times they occur in the form of abdominal cramps or may even simulate an attack of severe colic, necessitating the administration of a hypodermic injection of morphine. Several such cases are known to the writer and have clinically been mistaken by good ob-

servers for cholelithiasis when the x ray examination and the surgical operation revealed a penetrating ulcer. The intense burning may not always be spoken of by the patients in terms of pain. As is often observed in duodenal and pyloric ulcer, patients are awakened at night by an intense burning sensation in the stomach, so that they are forced to induce vomiting in order to obtain relief, yet they speak of this as burning but not pain.

Time.—These pains bear definite relation to the time of the intake of food. The time varies anywhere from one to three or five hours after meals. The nearer the ulcer to the cardia the earlier the pain. There are, however, exceptions to this rule. Late pains speak for duodenal ulcer; early pain coming on three quarters to one hour after partaking of food indicates an ulcer on the pars media of the stomach.

Hunger pains.—The appetite is usually good, often ravenous. The patients eat with a keen relish and enjoy their meals after which they experience for the first few hours a feeling of satiety and comfort. When the disease has lasted for some time, however, these patients begin to shun food for fear of the consequences. It is a daily occurrence to hear them remark that they would like to eat but are afraid when the disease has existed for some time. The sensation spoken of as hunger pain, which I would rather designate as hunger gnawing, should be differential from keen appetite, for this sensation is always present even in the patients who have lost their appetites. It is due to the hypersecretion present which is strongly hyperacid and is always present many hours after a meal when the stomach is ordinarily emptied. One often sees patients lean, haggard, with a dyspeptic facies, who have trained themselves to inanition and who have lost all desire to eat, yet in whom the hunger gnawing is always present and can be elicited on close questioning. These patients will then freely admit that they carry a few biscuits with them which they eat whenever this gnawing arises and are promptly relieved. Some patients take milk at night for the same reason, this likewise relieving them as soon as the acid is given an opportunity to combine with the food.

Location of the pain.—The location of the pain depends on the location of the ulcer. In duodenal and pyloric ulcers the pain is to the right of the midline or sometimes at the midline, and is referred upward into the right hypochondrium, sometimes to the right nipple, but never to the shoulder blade. When the ulcer is situated on the pars media or about the lesser curvature, the pain is referred to the left. If located on the posterior wall the pain is always referred to the back, and to the left of the spine. If a chronic perforation has taken place with adhesion to the pancreas the patient will always complain of a localized area of constant boring pain. (In one case a chauffeur attributed the pain to the pressure of a button on the back of his overcoat, on the left of his belt when leaning back on his seat).

Causation of the pain.—The belief that pain in ulcer is directly due to the irritation of the acid stills holds in the minds of many. This view is further strengthened by the relief obtained by the administration of alkalies. It is, however, of common knowledge that similar pains are present in

conditions of hypoacidity or even anacidity as achylia. Boas and others have long called attention to cases where the patients had obtained relief from alkalies and who had low acid values. The pain may also be relieved by the ingestion of a morsel of food, or water, or milk. Numerous experiments conducted by Hertz proved that instillation or irrigation with acid solution in ulcer cases in concentration as high as five tenths per cent. had no effect on inciting an attack of pain or aggravating the condition.

From these observations one cannot readily associate the acid with the primary cause of pain.

Modern advances in gastric physiology tend to the conclusion that ulcer pains are due to contraction of the stomach, pylorus and possibly the first portion of the duodenum. Hertz attributes epigastric pain to tension of the gastric musculature. He demonstrated that inflation of the stomach by means of a balloon introduced into the cardiac end of the stomach, leads to the sensation of fullness when the intragastric pressure rises to ten to fifteen mm. of mercury. Active or exaggerated peristalsis in a hypertonic organ causes increased tension and excessive intragastric pressure. The increased tension of the musculature of a stomach rendered irritable by disease gives rise to pain. By the balloon and x ray method of examination it has been observed that pain was always synchronous with the gastric and pyloric contractions. The subject under observation would always press a key as a signal of painful sensation, which would always correspond with the height of the contractions. Physiologists have further proved the presence of tonus changes and rhythmic contraction in the fasting stomach. Boldyreff in 1905 reported hunger contractions in dogs. Cannon and Washburn observed the same in man. Carlson classified the various types of contractions and tonus changes. He describes hunger contractions as powerful peristaltic contractions which arise at the cardiac sphincter and sweep down to the pylorus, increasing in strength as they proceed. Rogers and Hart in their röntgen examinations of a bismuth coated balloon introduced into the fasting stomach, also described the hunger contractions as vigorous peristaltic waves beginning at the cardiac end and sweeping over the whole stomach. The rhythmic contractions would occur at intervals of twenty minutes, and would always be associated with the sensation of hunger. We thus see that the pangs of hunger in the normal states are due to the periodical contractions and are synchronous with them.

The similarity of moderate ulcer pains to the strong hunger pangs in the normal person has long been observed clinically and led Moynihan to designate them as hunger pains. In diseased conditions, such as ulcer, the stomach is in a hyperirritable state, and any condition that will give rise to increased peristalsis will cause an increased tension and intragastric pressure resulting in pain. The acid plays a secondary rôle as it merely serves to stimulate contraction. The ulcer base in the deeper strata of the stomach contains sensory nerves which are not found in the

mucous surface of the stomach. When the ulcer is bathed in a medium containing free acid, whether of low or high concentration, increased peristalsis will result. Any other irritant, such as alcohol or a coarse food particle, will do the same.

An excess of acid in the duodenum, as emphasized by Hertz, prevents relaxation of the pylorus. This induced spasm of the pylorus and first portion of the duodenum by inhibiting the pyloric reflex adds to the increased tension resulting in hypertonus, hyperperistalsis and a marked increase in the intragastric pressure and pain.

The time of the occurrence of the pain is interesting as it adds additional weight to the factors entering into the causation of pain. It has been observed that the contractions are greater when most of the meal has passed out of the stomach several hours after the ingestion of the meal, the stomach being more than half empty. With the small calibre stomach the tonus is greater. The contractions are greater due to higher concentrations of the acid which occur at this time. The free acid remains uncombined, as most of it has already combined and passed out. In cases of hypersecretion the quantity and concentration constantly rise and one can often see, late in the digestion, the stomach full of secretion, with intense spasm and all the other previously mentioned pain producing factors. The relief from pain by alkalies is believed to be brought about in several ways. Some regard alkalies as a direct sedative to muscular contractions, that contrary to the acid, inhibit muscular contractions. However, it is well known that by neutralizing the acid, the stimulus to contractions is at once stopped. The pylorus becomes relaxed and the first portion of the duodenum becomes less irritable due to changes in the reaction on the chyme.

In conclusion it may be said that pain is due to: 1, muscular contractions when the stomach is in a hyperirritable state; 2, increased tonus; 3, increased intragastric pressure. The portion most irritated is the pylorus and the first portion of the duodenum. The time of most marked irritation is later, during digestion, when the stomach has more than half emptied itself, thus approaching the tonus changes and rhythmic contraction of the hunger state; 4, the acid as a contributory agent causes pain indirectly by stimulating contraction; alkalies control pain by inhibiting contraction and neutralizing the chyme.

(To be continued.)

Radium or Röntgen Ray Treatment.—William J. Young (*International Journal of Surgery*, April, 1920) states that there are definite fields of usefulness for radium and the röntgen ray both singly and collectively. Earlier recognition of diseases amenable to these agents and greater proficiency in their employment will result in a more comprehensive understanding of the indications, contraindications and limitations. The radiotherapist should be adequately trained in the diagnosis and clinical course of affections responsive to these agents as well as the technic of their application and the reactions which may be expected.

VOMITING FROM A SURGICAL VIEWPOINT.*

BY A. WIESE HAMMER, M. D.,
Philadelphia.

Surgeon to the American Hospital for Diseases of the Stomach;
Instructor in Surgery, Post-Graduate School of Medicine,
University of Pennsylvania, Polyclinic Section.

Thrown daily into contact with many surgical conditions and affections, I have been for some time past impressed with the fact that, while medical and surgical literature is not likely to regard vomiting as a symptom of special diagnostic import, my object in presenting what I may term these stray thoughts, is to invite attention to the subject of vomiting as forming, in not a few instances, a very important factor in the symptom complex of some of the major surgical maladies. In a brief exposition, such as this, it would be irrelevant to rehearse the undisputed facts of the physiology of vomiting; and to include a tabulated list of diseases engendering vomiting, the result of bacterial toxins in the blood, such as scarlatina, or diseases caused by poisons of nonbacterial origin, such as anemia, or to dwell upon the vomiting of pregnancy or emesis of gastric origin, would be superfluous.

In a consideration of this all important subject, in taking a superficial survey, we observe vomiting as merely an insignificant symptom at one end of the scale; at the other end, this ominous factor is a forerunner of death. Thus, we will first note briefly the nature of habitual vomiting, and then pass in review some of the more serious maladies, especially of a surgical character, in our effort to disprove the oft repeated assertion that the symptom of vomiting has little clinical worth, and for all practical purposes may be quite disregarded.

Let us first consider the matter of habitual vomiting, that peculiar condition which baffles explanation, usually occurring in females, apparently without cause and independent of organic disease. Food may be ejected in the midst of a meal or in the interval between meals. There is no esophageal spasm and no regurgitation of the stomach contents. Many clinicians assert that the condition is catching, and they place this peculiar entity—or perhaps non-entity—in the same category as habit chorea. This vomiting is to be differentiated from hysterical vomiting and from gastric neurasthenia. Taking this as the initial form of vomiting, and omitting mention of its occurrence in many conditions and maladies, we may with benefit at once discuss this symptoms as found in association with cerebral disease.

In acute or chronic cerebral lesions, vomiting may be absent or appear only at rare intervals, and it may not be attended with nausea. When it does occur, it is absolutely independent of food ingestion, is projectile in character, it often occurs in the early morning hours, and the tongue is not coated. The head cannot be raised from the pillow without incessant vomiting, although other symptoms are entirely dormant. Vomiting from cerebral conditions may at times occur when digestion is at its height and

closely simulate a case of indigestion, as in a sudden apoplectic seizure. It is thus almost impossible to determine its true character; but the age of the patient should be given serious consideration, and this important practical fact should always be borne in mind—that no matter how apparently simple an attack of vomiting may be, in a patient over the age of fifty, its oncoming should be regarded with suspicion. Sudden vomiting occurring in a middleaged person, or in a patient of advanced age, the emesis being painless, with or without nausea, with no evidence of gastric involvement, the ejected matter being made up of mucus or a watery fluid, should at once strongly suggest the likelihood of the occurrence of cerebral hemorrhage.

Such vomiting is not attended by the usual symptoms of relaxation, but the sthenic effects which usually attend apoplexy are present. If the usual collapse symptoms occur in persons of fifty or older, the affection is more likely to be of uremic origin. If the respiration be altered in rhythm, or of normal frequency, or slowed because of the intimate relation of the vomiting centre and the pneumogastric centre, the cause is more likely a central hemorrhage. Hurried breathing attends vomiting from other causes. Whether vomiting in cerebral affections, especially the incessant vomiting associated with cerebral tumors, is due to irritation of a special centre in the medulla, whether from stimulation of the pneumogastric centre itself, or engendered by vertigo, the result of the auditory nerve disturbance, produced by stasis, needs further investigation.

We need scarcely be reminded of the peculiar nature of exophthalmic goitre, whose three cardinal symptoms are tachycardia, goitre and exophthalmos. One should be extremely careful in pronouncing a diagnosis in some instances, for it is a well known fact that the goitre may be small or absent and the exophthalmos may be late in developing. In recent cases, before treatment is instituted, the clinical picture is fairly uniform, but the symptomatology may be most misleading if the affection begins suddenly or develops slowly. This may be especially true when the gastrointestinal symptoms are among the earliest and are in the ascendancy, that is, when metabolism is increased, with subsequent digestive changes, nausea, vomiting, and long continued watery stools. This vomiting is believed to be partly of nervous origin. There are quite a number of cases on record where abdominal pain, watery dejecta, nausea, and vomiting, forming part of a symptom complex of exophthalmic goitre, had been hurriedly diagnosed by practitioners as indiscretions in diet.

Intractable vomiting often occurs in biliary colic, often no other symptom, save epigastric pain, being present during the first twenty-four or forty-eight hours. In other cases, the patient is restless, has an anxious expression, the skin is cold and moist, perhaps cyanotic, vomiting soon occurs—at first the contents of the stomach, and, if the common bile duct is not obstructed, bile and gallstones follow. After the stomach contents have been ejected, repeated retching usually occurs.

*Read before West Philadelphia Medical Association, February 24, 1920.

The primary nausea and vomiting of acute appendicitis is reflex in character, and manifested early in the invasion of the disease. Almost invariably it is the second symptom of the development of the malady, pain being the first. As a rule there are a few efforts at emesis and the nausea then passes away. It is produced by an overdistended condition of the appendix, the result of retained infected matter in that portion of the gut. The secondary nausea, and often persistent vomiting, are really caused by peritoneal involvement, and their nature and persistence resemble in every way rupture of the stomach or intestine into the peritoneal cavity.

This thought invites attention to the peritoneum, and in acute peritonitis, distention, or meteorism is one of the earliest signs. It is Nature's way of splinting the intestines to minimize the pain of peristalsis. With decrease of peristalsis and intestinal absorption, putrefactive changes are encountered, and the bowels become overdistended with gas. In order to free themselves from this overdistention, reversed peristalsis occurs, the contents of the upper intestine forcing their way into the stomach to be finally disposed of by vomiting. This vomiting, which is an early symptom, often continues through the course of the disease—at first the stomach contents are expelled, then bile, and later, the contents of the small intestines, giving the vomitus a thin, pale yellow appearance. Frequently, just before the oncoming of the fatal issue, the vomited matter is of a dark brown color, although at times it is flocculent and resembles partly digested food.

The importance of vomiting as a cardinal symptom is well illustrated in certain cases of hernia, where it and abdominal pain may be the only two factors to attract the diagnostician's attention. Thus, in every case of vomiting associated with abdominal pain, it behooves the examiner to seek carefully for a hernia, as a small knuckle of the intestines may have become nipped in the hernial sac and be sufficient for the occurrence of these two appreciable symptoms. In incarcerated or obstructed hernia, obstruction takes place by the damming of feces or undigested food, the fecal current, but not the blood current, in the wall of the bowel being arrested. Nausea occurs, constipation that is not absolute is the rule, for gas is passing by the rectum and the vomiting is not fecal. In strangulated hernia, both the fecal current and the blood current in the wall of the bowel are arrested, and vomiting is an early and serious symptom. It may cease for a day or two, and especially before death, the result of profound prostration. The early vomiting is reflex in character, later it is regurgitant. First, the alimentary contents are expelled, then the bile, and lastly, the vomited matter is stercoraceous. Vomiting is seldom encountered in inguinal hernia, more often in femoral hernia, and still more frequently in obturator hernia.

With these few remarks relative to occlusion of the bowels, we naturally pass to the consideration of intestinal obstruction, recalling for the moment that acute intestinal obstruction may be caused by strangulation, the result of bands or cords, intus-

susception, twists and knots, strictures, peritoneal pouches, slits and fissures, also abnormal contents, as biliary calculi and enteroliths.

The stomach contents are first vomited, then the bile, and finally the duodenal contents, at first odorless but a few days later becoming fecal in character. A lesion in the upper part of the small intestine is characterized by the rapid oncoming of vomiting of a violent and expulsive nature, while obstruction of the large intestine exhibits vomiting as a later symptom, following generally tympanites, or, as is often the case, there may be eructations of gas without vomiting. The fecal nature of the vomitus in obstruction of the large intestine is to be ascribed to the regurgitated matter from the upper bowel, as there is no evidence to warrant the belief that the contents of the large intestine are ever vomited. In intussusception, fecaloid vomiting is the rare exception and certainly never the rule.

In connection herewith, it is of interest to note that a mere narrowing of even a small part of the intestine is only necessary to offer many of the cardinal signs and symptoms of total intestinal obstruction. Many years ago, Dr. William T. Smith, (1) professor of physiology in Dartmouth College, encountered a case of uncontrollable emesis in the person of a young woman, whose history at the time and whose past history failed to throw any light on her malady. The patient had no fever, there was no abnormality found upon urinary analysis, there was no local soreness; physical examination of all the organs was negative, and there was neither functional disturbance nor organic disease of the uterus, ovaries, or the appendages. For three weeks, nevertheless, there was headache with uncontrollable vomiting which later became fecal. By means of enemata, slight liquid discharges were noted. Dr. Charles B. Nancrede was called in consultation, a laparotomy was decided upon, but the operation failed to disclose the nature of the suffering. The patient died the next morning and at the postmortem examination a portion of the ileum, one inch long and five feet from the ileocecal valve, was found somewhat narrowed, apparently by cicatricial contraction, and the surface of the thickened membrane suggested distinctly a healed ulcer.

At this point it seems pertinent to the subject under review to say a word concerning regurgitant vomiting, followed the operation of gastroenterotomy. Because of improvements in surgical technic and a better understanding of abdominal surgery, this deplorable sequela is much rarer today than in times past. It is the result of one of several causes, or it may be due to a combination of factors, which result in a true, acute, intestinal obstruction. Prominent among these causes we may mention a too free and careless handling of the intestine, a kinking of the bowel at the point of anastomosis, and too firm a pressure caused by faulty clamping.

In concluding this subject of consuming importance, which has been treated very superficially, we should regard for a moment the varied symptomatology complained of by suffering women. The gynecologist knows only too well that diseases, de-

formities and malpositions of the female generative organs may give rise to chapters of symptoms, not the least conspicuous of which, in many instances, are nausea and vomiting. The symptoms may not point to an affection of the generative organs, but are often of a more general character, the type of which, on the one hand, is seen in neurasthenia and, on the other hand, in hysteria. Such nausea and vomiting occur always in the morning, and when alcoholism and Bright's disease are excluded from consideration, these symptoms, when occurring in the female, often indicate affections of the uterus, ovary, or appendages.

In this all too brief résumé of a most important subject, vomiting has been shown to be often a cardinal symptom of the first magnitude. I have only attempted to dispel the too frequent thought that vomiting is an unimportant symptom, and to point out the importance of using care in the interpretation of all cases of vomiting, suggesting that where the causes are not plainly indicated, an investigation should be made of every organ and bodily function, so as to determine the true cause of this important symptom.

FIBROMA OF THE MESENTERY.

Report of a Case.

BY A. JACOBY, M. D., F. A. C. S.,

New Orleans, La.

Solid new growths of the mesentery are extremely rare, and of those seen, according to Vance, the fibromata are the most frequent. In a search of the literature up to 1906, he found that in twenty-seven cases of solid tumors of the mesentery only had operation been performed, and of these thirty-three per cent. were malignant. Abdominal surgery and the diagnosis of intraabdominal growths, however, have shown such great progress since then, that more cases have been encountered and been successfully treated by operation.

In his report, he states that in nine cases there was a mortality of twenty per cent. which would be very much too high in this present operative era. In many of these cases the growths had attained a considerable size, because the patients did not seek advice until their attention had been attracted to the growth by some accident. They had been treated for a long time for indigestion or intestinal disturbance, because of failure to receive a proper examination. In the particular case reported, the patient, who was a tailor, had his attention attracted to the abdominal growth because of pain in that region. He pressed his hands against his abdomen hoping to obtain relief, when he felt the growth. In reporting this case, I wish to call attention to a method of anastomosis of the intestines, which is not original, however, but I am not able to give credit to the one to whom it is due.

CASE.—The patient, S. P., was referred to me

by his physician on November 15, 1918. His family history was negative. Personal history: He had had gonorrhoea, otherwise had never been ill, except with indigestion and an attack of jaundice in June, 1915. These attacks of indigestion were more of the nature of gaseous intestinal disturbances. The attack of jaundice came on rather suddenly, was not accompanied by pain, and there was very little increase of temperature. The jaundice remained for twenty-one days and from that time the patient stated that he had suffered from indigestion and a marked degree of constipation. After his attention had been attracted to the abdominal mass, he saw several physicians who treated him for intestinal disturbances and considered the mass a gas tumor.

On November 16, 1918, he was admitted to the Presbyterian Hospital and after the usual preliminary laboratory examinations he was taken to the operating room on November 18th for operative treatment. Under ether anesthesia, a right rectus incision was made and the tumor mass brought out of the abdomen. It was located in the mesentery and very close to the ileum, so that its removal could be considered only by a resection of that part of the ileum in the mesentery of which it was located. After determining the amount of ileum to be resected, the fecal material was removed from the points of excision and rubber clamps applied. The mesentery was first cut away from the bowel to be excised, so that any infection along that line might be avoided. The bowel was then excised with the cautery, tied, and inverted with several rows of chromic catgut and one of silk. The ends were placed side by side like the barrels of a shot gun and a lateral anastomosis done. This method of anastomosis does away with the danger of fecal stasis in the blind ends of the gut, one of the objections to the lateral anastomosis by the ends opposite to each other. Closure of the abdominal wall was done by the usual method with silkworm gut reinforcing sutures.

The patient had a very stormy convalescence which was accompanied by a severe and persistent hiccough for several weeks. The only relief obtained was from the almost constant use of morphine sulphate, one eighth grain, and atropine sulphate, one fifteenth of a grain, by hypodermic injections. An infection of the abdominal wall developed that also delayed his convalescence. He was given a proctoclysis of glucose five per cent. and coffee equal parts, to make one pint, every six hours for nearly three days, when it was discontinued and small amounts of clear meat broth, tea, well sweetened lemonade, coffee, and fruit tablets were allowed. On November 22nd the bowels moved voluntarily, a large liquid stool resulting. From that time on the diet was increased until on November 25th he was taking a full diet. On January 15, 1919, he was discharged as cured. Two weeks later, he resumed his usual occupations and remained well until April 1st when a marked jaundice suddenly developed which became so intense that a diagnosis of malignancy was made and an exploratory laparotomy advised. It was believed that drainage of the gallbladder or the anastomosis of

the gallbladder to the duodenum might overcome the jaundice and the resulting toxemia. A laparotomy was performed on April 4, 1919, at the Hotel Dieu and after a thorough exploration, only a small contracted gallbladder was found without any obstruction of the ducts. The site of the anastomosis of the intestines was found to be very satisfactory. After his recovery from the operation, though Wassermann reactions had always been negative when made by different observers, the jaundice yielded to three injections of neosalvarsan and mercurial inunctions. He has remained well ever since, with the exception of another attack of jaundice which yielded to the salvarsan treatment. The report of the pathologist was: Fibroma with hyaline changes; tumor measured 15 cm. by 12.5 cm. by 8.75 cm., weight 132 grams; bowel length, 42.5 cm.

LONDON LETTER.

(From our own correspondent.)

*London Association of the Medical Women's Federation.—
Death of Sir Henry Burdett.*

LONDON, May 4, 1920.

A meeting of the London Association of the Medical Women's Federation was held at the rooms of the London Society of Medicine, 11, Chandos street, W., on April 20, last. Dr. Helen Boyle was in the chair. Dr. Louisa Garrett Anderson, formerly chief surgeon at the Military Hospital, Endell street, gave an account, illustrated by lantern slides, of the work at that hospital from 1915 to 1919. She said that the surgical work might be described as falling under three heads. In 1915 to 1916 large numbers of head wounds were received, and fractured skulls, with every kind of complication, were treated. In 1916 and 1917 compound fractures of the thigh were numerous, while in 1918 a series of penetrating wounds of joints, especially the knee joint, were common.

It is interesting to note that Dr. Anderson is enthusiastic as to the value of bipp, which from all accounts seems to have been the greatest antiseptic success of the war. Dr. Anderson said it was first tried in 1916. It was used afterward in a large number of cases of compound fracture, and always with the best results. It replaced other disinfectants. It aided in ward work enormously, as cases which had previously been dressed twice or thrice daily were left undisturbed with bipp for a week or more. It apparently altered the prognosis of cases and shortened the time of treatment in hospital. Over 26,000 men passed through the hospital, and 7,000 operations were performed; 300 beds were set aside for orthopedic cases. The speaker drew attention to the fact that the treatment of fractured thighs and wounds complicating joints had been revolutionized by Sir Robert Jones and his disciples, Major M. Sinclair, and Major J. Everidge. In 1914 a case of compound fracture of the femur was a source of infinite anxiety to the surgeon and great suffering to the patient, it meant dressings at frequent intervals, drainage tubes, constant operations for the removal of sequestra, and, at the end of months of misery, a weak leg,

considerably shortened, possibly with a stiff knee. The modern method of thorough preliminary investigation and cleaning, following by the application of bipp to the wound, suspension on a net bed or a Balkan frame, a wellfitting Thomas splint, and early movement of the knee, was incomparably better. The evolution of technic for dealing with penetrative wounds of joints was equally striking. In 1918 it was not uncommon to regain a full, or almost full range of joint mobility.

* * *

A great organizer, a great financier and a great personality has just passed away in the person of Sir Henry Burdett who died in London on April 29th last, at the age of seventy-three. Although educated for the medical profession, and in fact passing all his professional examinations, he never took a degree or qualification in medicine or surgery, and yet he probably did more for medicine than any man of his time. For the first six years of his working life, and it was indeed a working life, he was superintendent and secretary of the Queen's Hospital, Birmingham, and for the next six years filled a similar position at the Seaman's Hospital, London. During his six years' term of the latter post, he displayed exceptional financial ability and organizing powers. He succeeded in raising the income of that institution from £7,000 to £13,000 a year.

His chief and most lasting memorial will be his work in aid of philanthropic and social causes. He was the founder of the Royal National Pension Fund for Nurses, which proved a conspicuous success. In less than ten years, 5,000 nurses joined the fund, the endowment reached £73,000, the total investment amounted to £384,000; while the pensions policies numbered nearly six thousand, and the sickness policies, nearly two thousand. Nor was this all Sir Henry Burdett did for the immediate benefit of nurses. He was one of the first to organize a system of training nurses according to modern ideas, and in many other directions he labored to raise the status of their profession. He did almost as much for the hospitals as for the nurses and took the deepest interest in the Hospital Sunday Fund. He was always a firm believer in the voluntary hospital system and in the existing hospital crises, although enfeebled by illness, employed his pen to insist that ample funds could be raised to continue the voluntary system. He founded and was editor of the *Hospital* and he established *Science Progress* and a nursing journal. He published many volumes on the activities and organization of hospitals and on the multiform aspects of the nurse's life and work. He is best known in America and all English speaking countries by his *Hospitals and Charities*, a year book of philanthropy, which contains a stupendous amount of special information and is recognized as a leading book of reference on the many subjects discussed in its pages. Sir Henry Burdett was assuredly one of the great workers of the age and like several other distinguished men and intense workers did a large proportion of his literary labors while the world in general was sleeping.

GENERAL GORGAS.

The death of Dr. William Crawford Gorgas marked the passing of a worker in the field of medicine whose achievements did much to show the world the importance of medicine in relation to human progress. Through his ability as an organizer he took advantage of the advances that had been made in the laboratory, the clinic, and the researches in sanitation, and applied them to the practical task of making possible the construction of the Panama Canal. He thus achieved lasting fame and did great service to humanity. The painstaking work of all the men who had furnished the material for him was not lost. The pragmatic application of their findings gave real value to their results. It took medicine into the realm of national achievement and into every avenue of commerce. His was a really great work.

He brought to public attention the power of medicine when applied on a large scale. The results of his operations involved cities and armies. He cleaned up the fever laden canal zone; he eradicated some of the deadliest diseases known to mankind; he converted the most loathsome spot on the American continent into a place of beauty and a pleasure resort. He was triumphant after the French had twice failed. He succeeded in the face of sceptical criticism, when wise men predicted failure. His was the courage of facing an apparently hopeless task. Proud should America be of having contributed such a man to the field of medicine.

His peace time achievements were constructive. For these he will not be forgotten. Many of the rules he set in the construction of the canal were carried over and used during the war.

Here too he was willing to learn and take advantage of the work done by medical men in other armies. Observers were stationed with the Allied armies in the field and their findings were brought back to the American army so that the American troops would get the benefits. In the meanwhile under his direction the organization of the units was rapidly and skillfully accomplished and when hostilities began the troops had the best care of any of the armies in Europe. All this with the disadvantage of the army being across the sea, thousands of miles away. All medicines, foods and supplies had to be transported from America to the great body of men in the American army. Much of this success was due to the close harmony between the Red Cross and the army. Gorgas made this possible. Lives were saved. While the practitioner is beloved for the work he does in daily contact with his patients, the admiration of a nation is tendered General Gorgas for the work he did for the masses and a permanent place in the annals of medicine.

Born in Mobile, Ala., in 1854, General Gorgas was educated at the University of the South and received his medical training in New York at Bellevue. In 1880 he was appointed a surgeon in the U. S. Army. It was during the Spanish war that his work first brought him general attention. He was serving as health officer of Havana when he seized upon the discovery of the transmission of yellow fever by mosquitoes, and proceeded to clean up the city. Then followed his work on the Panama Canal. In 1913 General Gorgas went to South Africa at the request of the British Government to investigate conditions in the Rand Mines, where thousands of natives were dying of pneumonia. In 1914 he was appointed Surgeon General of the United States Army. His last campaign was waged against yellow fever strongholds in Ecuador, under the auspices of the International Health Board of the Rockefeller Foundation.

ICTEROGENIC SPIROCHETOSIS.

The morbid process called Weil's disease, whose pathogenic agent was discovered by a Japanese, shows in apyretic cases a normal coagulation while in others the coagulation appears in from five to twenty minutes, but it never appears to be delayed as it is in acute red-yellow atrophy of the liver.

Usually the globular resistance is increased but there are periods when this resistance is decreased and this is probably the cause of the anemia observed from time to time in the advanced periods of the disease. On the other hand, the anemia occurring at the onset of the affection is due to a relaxed hematopoiesis. Examination of the bone marrow and splenic pulp shows that the erythrocyte is active in both structures and the manufacture of red blood corpuscles is lessened. No myeloid element can be detected in the spleen although it would appear that some megakaryocytes are present and there is an intense production of macrophagocytes. While in cases undergoing a rapid evolution the size of the spleen varies little, it is quite otherwise in the cases with a slow evolution; the latter is a sclerosis of the splenic pulp. This sclerosis is independent from the lymphatic elements and seems to be related to the multiplication of the macrophagocytes. The lymph nodes usually offer a follicular hyperplasia and a multiplication of the large mononuclears without macrophagia, but with cells containing basophile grains. The condition of the lymphatic lymph node of the hilum of the liver is different. Here necrosis and bacilli are present. It would seem as if this were consequent upon a bacterial infection of the biliary tract superadded to the infection by the spirochetes.

The liver is much larger than normal, varying between 1650 to 2350 grams, while its color varies between a yellowish dark green to that of Sienna earth. The biliary tract is not pathologically changed. The gallbladder contains little bile and may contain blood. In cases where death occurs after the second day, the tissues near the central vein are greenish while those near to the Kernian spaces are brown. The greenish tint is due to an accumulation of pigment. Microscopically, the icterogenic spirocheta produces a hyperplasia of the hepatic parenchyma with hyperbiligenia. When death takes place at the onset of the process a multiplication of the trabecular cells may be the only morbid change noted, nevertheless there is also a moderate steatosis—in acute red-yellow atrophy the steatosis is more marked—the dislocation of the cells of the lobules is very characteristic.

All these lesions are found in the acute cases, while those arising in cases having a slower evolution are as follows. There is a decrease in the size of the cells, a slight lymphocytic infiltration, a necrobiosis of certain hepatic cells, which are undergoing multiplication, slight steatosis, accumulations of pigment in the trabecular cells and dilatations of the intercellular canaliculæ. At the onset of the disease the spirochetes are numerous in

the liver and this is in relation to the appearance of the icterus. The kidneys are usually involved, the weight of each organ varying between 180 to 325 grams. There is an interstitial reaction tending to sclerosis and epithelial degeneration. The glomerulæ remain intact, while the tubuli contorti are invariably involved. In subjects dying from aneuria a singular fact is that the tubuli contorti are free from bile pigment, therefore indicating that there is a renal inhibition and in these cases the hepatic lesions are profound. The lesions of the tubuli contorti are certainly due in part to the spirochetes which are eliminated by the tubuli and indirectly to the lesions of the hepatic cells.

CANCER OF THE MIDDLE EAR.

The positive diagnosis of malignant disease of the middle ear and the external auditory canal in its bony portion may be difficult at the onset of the process, and microscopical examination at this time is the only means at our disposal of ascertaining the true nature of the granulations. Later, pain, facial paralysis, and rapid cachexia will lead to a suspicion of malignancy and a biopsy should be made. It is quite possible that radiography will render assistance when a more perfect technic has been devised, as it is hoped that by this means will be revealed the process taking place in the bony walls of the external ear as well as in advanced neoplasia where there are few or indefinite symptoms.

The various hearing tests will show the state of the auditory apparatus. The tests for nystagmus, in particular, will give useful data as to the state of the vestibular labyrinth, from which, in cases of vertigo, one will be able to ascertain how much this depends upon the state of the middle ear and how much it may depend upon central compression only. Caloric and rotatory nystagmus must likewise be searched for, although the pathogenesis of these symptoms is still a moot question. It may be simply stated that if nystagmus produced by the injection of cold water into the diseased ear does not give rise to rotatory nystagmus on the opposite side, it should not be hastily concluded that a destructive process is going on in the labyrinth. In point of fact, the neoplastic masses interposed may form a kind of cushion against the thermic action and thus warp the result. Consequently, in these cases nystagmus must also be provoked by gyration. If then there is no nystagmus reaction it will be perfectly logical to conclude that there is destruction of the vestibule. The search for voltaic nystagmus must not be overlooked and in this test Babinski's method should be followed.

The only differential diagnosis to make is that between granulations of the cavity of the tympanum, polypi, and cholesteatoma, but the latter is less rapid in evolution and does not bring out the early cachexia as is the case in malignant disease. Microscopically, in cholesteatoma the cells are of the pavement type, since the process is formed by desquamation of the epidermis and never will horny globes be found which are characteristic of epithelioma. The question of primary cholesteatoma would not be discussed as it is still a debatable subject, some observers maintaining that it is a true neoplasia.

PSYCHOLOGY AND INTERNATIONALISM.

The American National Research Council, based upon forty or more scientific societies to promote the interests of pure and applied science, numbers among them the division of psychology and anthropology, which division has formulated a number of cooperative projects. Here are two: The examination of four alien groups, Mexicans, Scandinavians, Sicilians and Japanese; some two thousand to be scientifically examined so as to shed light on the problem of assimilation in the United States.

The second plan is to send an expedition to Central Africa in the Congo upper regions to study the aborigines untouched by civilization. A language-learned psychologist will head the expedition. If the aborigines could visit Europe at present they might insist on the incoming scientists being examined for freedom from the germs of that exhausting disease—civilization.

SANITATION AND GOOD WORK.

Nothing annoys a patient who has made an auto-diagnosis of heart disease, brain fag or lung trouble, to be told that the whole source of mischief lies in constipation or his kidneys. It is the same with many social industrial reformers. They study fatigue and efficiency, mind measuring, better hours, better homes, but, if told that toilet rooms, revolting in appearance and difficult of access, were often accountable for faulty work and discontent, they would not believe. But, for the Safety Institute of America no study is insignificant, and they consider a decent sanitary equipment as a valuable asset to any work place. Employees reluctantly yield to Nature's demands when the toilet is uncleanly, and it is hard for them, when, at the end of the day, they have to go unwashed among the people in crowded cars and ferries.

Toilet rooms should be placed where they are exposed to light and air. Sunlight is a powerful germicide and disinfectant. If artificial light has to be used it should penetrate to every corner so showing up dirt and inducing thorough cleanliness by flushing or scrubbing the floor. It should be easily accessible, yet not too prominent, because some false modesty still exists, many girls saying

they would rather die than walk to an obvious toilet through a room crowded with men. These do die generally of architectural blunders, though relations term it stomach trouble, and vendors of patent medicines grow rich from the sale of headache powders and liver tonics, the necessity for which is not in hard work but wretched sanitary equipment.

News Items.

Cambridge University Faculty.—Professor James Thomas Wilson has been elected professor of anatomy in Cambridge University to succeed the late Professor Macalister.

Diplomas in Psychological Medicine.—The University of London is about to institute a diploma in psychological medicine, the standard for the diploma being about that required by the University of Cambridge.

Medical Journalism.—Professor Giuseppe Guicciardi of Reggio Emilia has succeeded the late Professor Augusto Tamburini as editor of the well known journal of psychiatry, *Rivista Sperimentale de Freniatria*.

Royal College of Surgeons in Ireland.—Mr. Edward H. Taylor, regius professor of surgery in Trinity College, has been elected president and Sir W. I. de C. Wheeler has been elected vice-president of the Royal College of Surgeons in Ireland.

Award to Dr. Theobald Smith.—The M. Douglas Flattery Medal and prize of \$500 have been awarded by the Harvard Corporation to Dr. Theobald Smith, formerly of Harvard University, in recognition of successful scientific research resulting in the prevention of disease and the conservation of health.

Correction.—The statement was made in a recent issue that the proposed International Health Office to be established under the health section of the League of Nations would be located in London. The International Health Office is, however, to be established at the seat of the capital of the League of Nations.

North Carolina Medical Meeting.—The Medical Society of the State of North Carolina recently held its annual meeting, under the presidency of Dr. Carl V. Reynolds, of Asheville, and elected the following officers: President, Dr. Thomas E. Anderson, Statesville; vice-presidents, Dr. Charles S. Lawrence, Winston-Salem; Dr. William H. Ward, Plymouth; Dr. John M. Manning, Durham; secretary-treasurer, Dr. Benjamin K. Hays, Oxford (re-elected).

Venereal Diseases Conference.—A Pan-American conference on the control of venereal diseases will be held in Washington, probably in December under the auspices of the American Red Cross, the United States Public Health Service, the United States Interdepartmental Social Hygiene Board, and the American Social Hygiene Association. The work of the conference will deal with three different groups of problems in the control of venereal diseases, namely, the purely scientific, the administrative, and those which have particular public interest.

Massachusetts Medical Meeting.—The one hundred and thirty-ninth annual meeting of the Massachusetts Medical Society was held on June 8th and 9th in Boston, under the presidency of Dr. Alfred Worcester. The officers for the preceding year were reelected, with Dr. Frederick E. Jones as the vice-president.

West Virginia State Medical Conference.—The West Virginia State Medical Association held its annual meeting in May, when the following officers were elected: President, Dr. J. Howard Anderson, of Marytown; vice-presidents, Dr. Hubert E. Gaynor of Parkersburg; Dr. S. G. Moore, of Elkins; Dr. Charles O'Grady, of Elkins; secretary, Dr. Robert A. Ashworth, of Moundsville; treasurer, Dr. H. G. Nicholson, of Charleston.

Parkin Prize Offered.—The Royal College of Physicians of Edinburgh announces a competition for the Parkin prize of 100 pounds, which will be awarded for the best essay on the curative effects of carbonic acid gas or other forms of carbon in cholera, for different forms of fever and other diseases. The prize is open to competitors of all nations. Essays must be in the hands of Dr. J. S. Fowler, the secretary, not later than December 31, 1920.

Eugenics Research Conference.—The eighth annual meeting of the Eugenics Research Association was held June 25th at Cold Spring Harbor, Long Island, under the presidency of Dr. Stewart Paton, of Princeton. Dr. Irving Fisher was elected president for the ensuing year, and plans were made for the transformation of the *Eugenical News*, an eight page monthly, into a quarterly *Journal of Eugenics*, under the auspices of the association.

Greek Hygienic Congress.—The first Pan-Hellenic Congress of Hygiene and Demography will be held at Athens from April 25 to 30, 1921, under the presidency of Professor Phocas. There will be sections in public health, individual hygiene, military and naval hygiene, demography, infant hygiene, and prophylactic hygiene. An international exhibition of hygiene and medical industry will be opened at the same time as the congress and will continue until June 25th.

Honorary Degrees for Medical Men.—In connection with the annual meeting of the British Medical Association in Cambridge, the council of the University Senate has proposed for the degree of LL. D. *honoris causa* the following distinguished members of the medical profession: Dr. Harvey Cushing, professor of surgery, Harvard University; Dr. Simon Flexner, director of laboratories, Rockefeller Institute for Medical Research; the late Major General William C. Gorgas, former president of the American Medical Association and Surgeon General of the U. S. Army; Sir T. Clifford Allbutt, K. C. B., regius professor of physics; Dr. Jules Bordet, president of the Faculty of Medicine and director of the Pasteur Institute, Brussels; Dr. A. Calmette, director of the Pasteur Institute, Lille; Dr. P. Giacosa, professor of materia medica and experimental pharmacology, University of Turin; Sir G. H. Makins, G. C. M. G., president of the Royal College of Surgeons of England; Sir Patrick Manson, G. C. M. G.; Sir Norman Moore, president of the Royal College of Physicians of London.

Association of American Physicians.—At the annual meeting of the Association of American Physicians, held in Atlantic City, the following officers were elected: President, Dr. William S. Thayer, of Baltimore; vice-president, Dr. Herbert C. Moffitt, of San Francisco; secretary, Dr. Thomas McCrae, of Philadelphia; recorder, Dr. Thomas R. Boggs, of Baltimore; treasurer, Dr. Joseph A. Capps, of Chicago.

Smallpox in Virginia.—During the first four months of 1920 there were 1,821 cases of smallpox reported in the State, with six deaths, compared with 770 reported cases in the same period of 1919 and ten deaths for the entire year of 1919. During 1917 the disease caused but two deaths, while in 1918 six deaths were attributed to it. In January, 1919, there were 129 cases against 467 in January, 1920. In February, 1920, the disease reached its apex for the season with 703 cases against 113 for the corresponding month of last year. In March the figures were 326 against 261 for March, 1919, while in April they were 325 and 267 cases, respectively. During April of this year smallpox was reported in thirty-four of the ten counties and during the year it has appeared in approximately half of the counties of the State.

Flechsigs' Jubilee.—Dr. Paul Flechsig, the noted Leipzig anatomist and psychiatrist, celebrated the fiftieth anniversary of his graduation on May 23rd. When assistant at the University Physiological Institute his first considerable work on Conduction Paths in the Brain and Spinal Cord attracted attention. In 1882 he took over the Neurological Clinic, built and furnished on plans drawn up by himself, whose chief he still is. Flechsig holds an honorary doctorate in the Faculty of Exact Sciences at Oxford and is an honorary member of learned societies in Dorpat, Dresden, Florence, Kieff, London, Munich, Paris, Petrograd, Rome and Vienna. On the day of his jubilee the firm of Georg Thieme, of Leipzig, issued as a Festschrift the first volume of a monumental work on the Anatomy of the Human Brain and Spinal Cord on a Myelogenetic Basis, on which the veteran psychiatrist has been intensively engaged for ten years.

DIED.

BLADES.—In Hornell, N. Y., on Monday, June 28th, Dr. John Wesley Blades, aged sixty-five years.

DAVENPORT.—In Vancouver, B. C., on Monday, May 31st, Dr. George Edwin Davenport, aged fifty-seven years.

FRITCHEY.—In Harrisburg, Pa., on Thursday, June 24th, Dr. Charles Albert Fritchey, aged forty-five years.

GORGAS.—In London, England, on Sunday, July 4th, Major General William C. Gorgas, U. S. Army, aged sixty-six years.

MILNOR.—In Warrensville, Pa., on Thursday, June 24th, Dr. Robert H. Milnor, aged fifty-two years.

PRICE.—In San Francisco, Cal., on Saturday, June 19th, Dr. Thomas Linton Price, aged fifty-four years.

SCHUMANN.—In Oakland, Cal., on Saturday, June 19th, Dr. H. Schumann.

STRAUGHN.—In Jersey City, N. J., Dr. Frederick Straughn, aged seventy-five years.

TOMES.—In Brooklyn, N. Y., on Monday, June 28th, Dr. William Austin Tomes, aged fifty-five years.

Book Reviews

ORGANIC CHEMISTRY.

The Preparation of Organic Compounds. By E. DE BARRY BARNETT, B. Sc. (Lond.), A. I. C. With Fifty-four Illustrations. Second Edition. Philadelphia: P. Blakiston's Sons & Co., 1920. Pp. vi-273.

In this, the second edition of *The Preparation of Organic Compounds*, the author has made no fundamental change in the size or scope of his book. Several additions have been made, however, which increase its usefulness. The inclusion of a short description of larger sized apparatus suitable for use in the laboratory resulted from the author's experience during the war, when he found that few chemists had any idea of what apparatus to use when it became necessary to handle materials in unusually large quantities. Some of the apparatus described may be regarded as crude, but the average manufacturing plant is seldom fitted with the latest refinements and the practical chemist must adapt himself to his environment. Chemical preparations can be carried out in saucepans and jam pots quite as successfully as in the more conventional and more expensive beakers and basins. The description of the chemical processes is less full than in most books on organic preparations but the details given are sufficient to enable the student to carry out the preparation successfully, without being so exhaustive as to reduce the work to mere mechanical routine. The bibliography will appeal to the more serious minded student. The selection of a considerable number of preparations from the patent medicine literature, with the hope of familiarizing the student with this neglected branch of the literature, is to be commended. To the beginner and to the advanced student in organic chemistry the present volume will serve as a valuable laboratory manual and as a companion volume to the usual theoretical textbooks.

THE PSYCHOLOGY OF THE DOCTOR.

Das autistisch undisziplinierte Denken in der Medizin und seine Überwindung. By E. BLEULER. Berlin: Julius Springer, 1919. Pp. iv-207.

Some time ago Bleuler treated of autistic thinking as the type of thinking of the egoistic psychoneurotic or psychotic. Now he comes forward to apply the term to the prevailing mental attitude in medical conception, treatment, prophylaxis, considerations of etiology, pathology and all that pertains to medical practice. He uses the term because he believes that medical thinking lags sadly behind in the precision, accuracy and persistent search after facts and facts only on which to base all activities and attitudes which should mark a profession so important and presumably scientific. He looks upon the physician as caught unconsciously in the desire to serve the patient's immediate need, to conform to the patient's wish and therefore pressed upon by the force of his own desire to maintain himself as physician and arise at once to the demand put upon him. Thus more and more he has become enmeshed in elaborated and meaningless formulistic prescriptions of various sorts, in interference with Nature's processes, a godlike assumption even of her activity, which

have blinded him to simplicity and actuality of facts as the governing factors of practice and theory.

Bleuler makes a plea for a humbler and more truly scientific position on the part of the profession, whether in the physical or psychic world, whether in the realm of pharmacology or in prescription of whatever sort, in understanding the reaction of individuals to any part of the environmental world. The physician has failed in this in physical diseases as in the mental. The quack has often superseded him because he has had naturally a better intuitive appreciation of the far-reaching psychology of interrelation and the part that a variety of facts play in the lives and health of men. The physician is a victim of a psychophobia which keeps him from a clearer investigation of actualities which are both psychological and otherwise scientific. The existing state of things is difficult of remedy, but Bleuler asks that a new type of disciplined thinking, investigative and constructive, shall become the rule. He points out the part the medical school and medical publications have in promoting this end.

SMALLPOX AND VACCINATION.

Half a Century of Smallpox and Vaccination. Milroy Lectures Before the Royal College of Physicians, 1919. By JOHN C. MCVAIL, M. D., LL. D., Edinburgh: E. S. Livingstone, 1920. Pp. iii-86.

A book from a Scotsman generally merits attention when it concerns a big subject. It may be dry or too erudite, but is reliable, so one settles down with easy mind to study smallpox as it was and is, vaccination as it was and is, and the control of smallpox in the present day.

The second lecture rebuts a contention that infantile vaccination, which protects the individual, makes smallpox "so difficult to recognize where it is not wholly prevented that the result is such spread of infection from missed cases disadvantageous to the community."

Careful statistics show smallpox to have increased gradually in power in the eighteenth century; to have reached its maximum in 1870-73, and since then to have "retrogressed in fatality, infectivity, and prevalence." He wisely remarks that it is too soon after the war to prophesy that we have seen its last consequences with regard to epidemic disease, but, whether it be of the American type with low infectivity or the severe type of the seventies, the means for meeting it are at hand.

THE MENDELIAN THEORY.

Mendelism. By REGINALD CRUNDALL PUNNETT, F. R. S. Fifth Edition. London: Macmillan Co., Limited. 1919.

A straightforward presentation of the Mendelian theory. In this, the fifth edition, are set forth the results of the work done on *Drosophila*, the fruit fly, by Professor Morgan, of Columbia University. These researches of Morgan's have done much to shed new light on the problem of heredity and many are of the opinion that it is one of the most far-reaching scientific discoveries of late years. The working out of hereditary traits up through man should have a direct practical bearing in the field of

medicine. On account of the great diversity in humans it is at times difficult to trace this. However, new work which has been done recently in the transmission of endocrine characteristics has opened a new field in the study of heredity and medicine. In order to realize the full significance of the work done by this painstaking monk on the common pea it is necessary to review the work as he actually did it. The extent of its influence, it should be recalled, is not limited to man and, as the author has pointed out, Mendel's findings have an economic value when applied to agriculture and the breeding of animals for live stock or other purposes.

This exposition presents the problem simply, tracing each step with care and leaving a cohesive picture of the problem of heredity as we understand it today.

HANDBOOK OF MEDICINE.

Wheeler's Handbook of Medicine. By WILLIAM R. JACK, B.Sc., M.D., F.R.E.P.S.G., Physician to the Glasgow Royal Infirmary, Lecturer in Clinical Medicine in the University, Glasgow. Illustrated. Sixth Edition. Edinburgh: E. & S. Livingstone; New York: William Wood & Co., 1920. Pp. v-561.

Since the first edition of *Wheeler's Handbook of Medicine* it has been found on the bookshelves of many physicians. This small compend has been more widely read as a ready reference work than many of the more unwieldy volumes. It is a convenient book both in size, composition, and brevity. Unfortunately, the present edition, the sixth, is badly printed. This is a drawback for a book of this type. While it may seem an unimportant point to criticize, and while allowances must be made for difficulties in regard to labor conditions and the scarcity of paper, it seems as though an unwise saving has been attempted. There are a few additions to the book due to a discussion of some of the diseases more commonly found during the war, but on the whole the general style and contents have remained unaltered.

MODERN PROGRESS.

The Story of Modern Progress. With a Preliminary Survey of Earlier Progress. By WILLIS MASON WEST. New York: Allyn & Bacon, 1920. Pp. xvi-701.

Fifty years ago an English schoolboy began his history composition by saying: "When Julius Cæsar landed in Britain all the world was in heathen darkness." It was—for the schoolboy. Term after term he plodded through his history of England. After that came the history of Rome, followed by that of Greece. There were no small histories of European countries, so that when he began the large ones, he never linked up dates nor made any connections, so he hazily imagined that other countries became civilized and started off as histories some time after his own, and he wearily took up Germany or said, thankfully, he had done France. The writers of schoolbooks made them as dry as possible, so that an anecdote was hailed with relief, and these retained in the mind, formed the basis of world knowledge.

It was a great task for the author to gather contemporary actors on the world's stage, not making its tragedies and comedies separately but all acting and reacting on each other as nations. Teachers will welcome its teaching, the schoolboy

will unconsciously benefit, and all use it as a useful reference. Naturally, one man cannot always judge rightly concerning the affairs of many nations in quite modern dealings because the babble of modern historians has not yet quieted down for the voice of Truth to be heard, but the reader feels that Professor West keeps an intent ear for her decisions, and so they walk together in glad trust through the Stone Age right away to the present century.

THE DEATH OF TITIAN.

The Death of Titian. By HUGO VON HOFMANNSTHAL. A Dramatic Fragment Enacted at Munich in Memory of Arnold Böcklin. Translated from the German by JOHN HEAD, JR. Boston: The Four Seas Company, 1920. Pp. ix-27.

It is the function of the masters in art and literature to present new and recreative views of life. They awaken us afresh to a fuller comprehension of its wealth and beauty as well as its darker meanings. This fragment reminds us of the depth and richness discovered by the great painter and portrayed permanently for the world's appreciation in his canvases. The poet dramatist who had dedicated to him this memorial has added to all this a quickening perception and lesson of his own.

The melody of the lines, which the translator has well reproduced, flows deep and full with the unbroken abundance and softness of a Venetian night in the master's own garden. Even the stage setting for the piece is indicative of the warmth of beauty in which the lines, in the mouths of the master's pupils, express more fully the field where Titian found his inspiration and expression. The poet has made to live again the vitality of the mind which could comprehend the sensuously beautiful in life in such vivid terms, to whom these things were the clothing of a spirit which breathed through them, renewed its courage and expanded its power in artistic mastery of them. The artist's more penetrating eye and warmer heart seizes and recreates this warmth and beauty for us.

More poignant still is a message from the dramatist's own conception. A high sustained note throughout this dramatic fragment gives a consummating force to the mere description of the painter's conception and expression. It lifts the reader's thought continually above the mere beauty, rich as that is, and above the sorrow of the pupils and members of the household. This is the reiterated contrast suggested rather than spoken between Gianano, young and handsome, in love with life and afraid of death, and the aged master. Gianano's fear is stronger than grief, the natural egotistical fear of one who has not yet found life and tried his powers. It arises when death suggests the uncertainty of all this. "Death! Death! . . . I've never stood so close to Death before!" Titian on the other hand has revived for work the best that he has yet done. "A radiance as a saint's shines through his pallor, as he paints and paints," eager only to secure these few more moments of creative activity. It is only outside that they mourn; the master is quiet and busy within. The sadness of death comes to those at the other side of life, where its achievements exist only in prospect and in uncertainty. The creator who has exhibited mas-

tery of his powers and of the world surrounding him is calm and even gay. His work is not torn from him, it only claims him up to the last moment when smilingly the brush is laid aside.

WILLIAM J. LOCKE.

The House of Baltazar. By WILLIAM J. LOCKE, Author of *The Rough Road, The Red Planet*, etc. New York: John Lane Company, 1920. Pp. ix-312.

It is curious how men depicting things by pen or brush or pencil always put in one little point of incompleteness to make it look more natural, more true to life. On a library shelf one book is askew or with a torn binding; in drapery, one fold hangs askew. In a shop whose window showed marvels in artificial flowers, I noted one group with a faded blossom, some petals fallen from another lay on the floor. Some such deliberate indication of imperfection is given in John Baltazar in his forcing himself to do what he has purposed without looking all round the question, but after a little acquaintance you feel that the human weakness only shows up the sturdy, dogged, cheerfulness he abundantly possesses. The author plays on the feelings of his readers in the same way as the skilled acrobat on the sightseers, who, when in a position of extreme danger nearly loses his balance, but does it intentionally to enhance the situation.

John Baltazar, mathematical professor at Cambridge, nearly leaves a waspish wife, who has not told him of her approaching motherhood, to go away with a bonnie pupil but flees to China instead, disappears, in fact, for nearly twenty years, and returning sets up as a hermit in a lonely cottage with his priceless Chinese manuscripts to write a marvelous book and continue mathematical studies. No news of the outside world comes to him, his faithful Chinese servant pupil is bound over to discreet silence, and only a Zeppelin bomb, destroying the cottage when the war has already been waging two years, brings him to a realization of the war, and knowledge of the fact of his possessing a motherless son, already war wounded, from the girl pupil—now over thirty—who is a hospital nurse and recognizes the son's name among her charges.

The erudite labor of many years was all destroyed by the bomb, but the countershock of his country's peril arouses him to devote himself wholly to her, a golden thread of love in the way of a determination to tenderly coax the nurse, Marcelle, to marry him, his consolation. Tremendous success attends his politicomilitary efforts. He is one of the coming men; his dream of helping is realized. But his new found soldier son becomes entangled with the beautiful wife of a politician. She is bent on being a leader, and delights in political secrets. She has induced the son to elope with her; his military career will be ruined. They are on the railway platform; the train is leaving in a few minutes but toward them is hastening John Baltazar, just in time to hurry his son off the scene and face the husband of Lady Edna Donnithorpe, whom he forces to believe that he—John—is the intending eloper. The snarling, scandal loving politician does not really believe, but is greatly glad to ruin his enemy, so there stands the hero facing the third crisis in his life. Sweet love refused for the honor

of a girl; the fruits of long study rudely destroyed, a dream of helping his country vanishing, all his promises fulfilled, no reward to the promiser save seeming defeat. He will return to China—alone. Then, at 2:30 a. m., a most dismal hour to be housed with disappointment as a companion, comes Nurse Marcelle to give him what he has so patiently waited for and scarcely hoped to win. She will go with him, and life shall reblossom in the land of his exile.

In one part of the book he deprecates his name of John, equally so its diminutive Jack of melodramatic fame, but, from much reading, the reviewer guessed a John could not go wrong, for all heroes called in fiction are invariably strong, and indomitable right away to the end of life and the book.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE FOOLISH LOVERS. By ST. JOHN G. ERVINE, Author of *Changing Winds, John Ferguson*. New York: The Macmillan Company, 1920. Pp. iii-403.

DIE KINDERTUBERKULOSE IHRE ERKENNUNG UND BEHANDLUNG. Ein Taschenbuch für praktische Ärzte von Prof. HANS MUCH. Leipzig: Verlag von Curt Kabitzsch, 1920. Pp. v-35.

MASKS. *With Jim's Beast, Tides, Among the Lions, The Reason, The House.* One Act Plays of Contemporary Life. By GEORGE MIDDLETON. New York: Henry Holt & Co., 1920. Pp. 3-227.

O. HENRY MEMORIAL AWARD PRIZE STORIES, 1919. Chosen by the Society of Arts and Sciences. With an Introduction by BLANCHE COLTON WILLIAMS. Garden City and New York: Doubleday, Page & Co., 1920. Pp. xvii-298.

THE MICROBIOLOGY AND MICROANALYSIS OF FOODS. By ALBERT SCHNEIDER, M. D., Ph. D. (Columbia University); Professor of Pharmacognosy, College of Pharmacy, University of Nebraska, etc. Illustrated. Philadelphia: P. Blakiston's Son & Co. Pp. v-262.

EREWON REVISITED TWENTY YEARS LATER. Both by the Original Discoverer of the Country and by His Son. By SAMUEL BUTLER, Author of *Erewhon, The Way of All Flesh, Life and Habit*, etc. With an Introduction by MOREBY ACKLON. Illustrated. New York: E. P. Dutton & Co. Pp. xxvii-304.

LES ALLURES CLINIQUES DE LA SYPHILIS ET LES FORMES DE PARALYSIE GÉNÉRALE CONSECUTIVE. Par Dr. LUIGI ROMOLO SANGUINETTI, de la Faculté de Médecine de Paris; de la Faculté de Médecine de Sienne (Italie); ex-interne de l'Asile d'Alienes et de l'Institut de Pathologie Générale. Paris: Jouve & Cie, 1917. Pp. i-287.

ESSENTIALS OF PHARMACY, WITH QUESTIONS AND ANSWERS. By CLYDE M. SNOW, Ph. G., A. M., Associate Professor of Pharmacy, University of Illinois School of Pharmacy; Graduate Instructor in Pharmacology. University of Illinois College of Medicine, etc. St. Louis: C. V. Mosby Company, 1919. Pp. xiv-734.

LEHRBUCH DER SPEZIFISCHEN DIAGNOSTIK UND THERAPIE DER TUBERKULOSE. Für Ärzte und Studierende von Dr. BANDELIER, Chefarzt des Sanatoriums Schwarzwaldheim in Schomberg bei Wildbad, und Prof. Dr. ROEPKE, Chefarzt der Heilstätte Melsungen, Facharzt für Lungen und Halskrankheiten in Kassel. Mit einem Vorwort von Winkl. Geh. Rat Prof. Dr. R. KOCH, Exzellenz. Zehnte Auflage. Mit 25 Temperaturkurven auf 7 lithographischen Tafeln, 2 farb. lith. Tafeln, und 6 Textabbildungen. Leipzig and Würzburg: Verlag von Curt Kabitzsch, 1920. Pp. xi-501.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Nutrition and Public Health with Special Reference to Vitamines.—J. F. McClendon (*American Journal of the Medical Sciences*, April, 1920) believes that the nutrition of some individuals, especially infants, is not ideal, and that the high cost of living is leading to worse nutrition. A large part of the population has unconsciously depended on the presence of milk in an otherwise inadequate diet, and the decrease in milk consumption that is now taking place is to be viewed with alarm. The supply of fresh green vegetables is not sufficient to be a substitute for milk. Grass is not adapted to human alimentation except in the form of sprouted grass seeds. In the sprouting of seeds vitamines are synthesized in the young leaves and a quick crop of vitamines may be obtained without the necessity of planting the seeds in the ground. Wheat or rye, sprouted until the shoot extends an inch beyond the grain and heated in water to 70° to gelatinize the starch, forms a cheap, convenient, and palatable source of vitamines. The seeds may be freed from bacteria before sprouting. Since beef fat is about as valuable a source of vitamines as is butter, beef drippings and fat should be eaten rather than thrown away, and the same applies to some other animal fats. Prolonged cooking of fresh foods should be discouraged, but all canned goods should be heated to boiling before they are served, to destroy toxins of bacillus botulinus that might be present, unless a competent inspection of the goods has been made.

The Sippy Treatment of Peptic Ulcer.—Julius Friedenwald and Theodore H. Morrison (*Southern Medical Journal*, May, 1920) state that this treatment has yielded most gratifying results in a large number of cases. Sippy's treatment consists in protecting the ulcer from the acid corrosion of the gastric juice until it has healed. This is accomplished by maintaining a neutralization of the free hydrochloric acid from early in the morning until late at night. The neutralization is effected by frequent feedings and the administration of alkalies, given freely and at frequent intervals. Nourishment is given from the start. The patient remains in bed for three or four weeks. Three ounces of a mixture of equal parts of milk and cream are given every hour from seven a. m. to seven p. m. After two or three days soft eggs and well cooked cereals are gradually added until in ten days the patient receives three ounces of milk and cream mixture every hour, three or four boiled eggs, and nine to twelve ounces of a cereal each day. Cream soups of various kinds, vegetable purees, and other soft foods may be substituted now and then as desired. One egg is given at a time and three ounces of a cereal at a single feeding, the cereal being measured after it has been prepared. The cereal and eggs are given alternately and taken at the same time as the three ounce mixture of milk and cream. The total bulk of each feeding should not be over

six ounces. After a longer or shorter period, according to the condition of the patient, a large variety of soft and palatable foods may be used, such as jellies, marmalade, custards, and cream, but the basis of the diet should be milk and cream, eggs, cereals, vegetable purees, and bread and butter. Alkalies are administered from the beginning of the treatment, between the feedings, to neutralize the acid secretion; powders of heavy calcined magnesia, ten grains, with sodium bicarbonate, ten grains, being alternated with powders of bismuth subcarbonate, ten grains, and sodium bicarbonate, thirty grains. It is also advisable to give the powders every half hour after the last night feeding for a number of doses. If the acidity is not promptly controlled ten grains of sodium bicarbonate may be added to each powder until it is controlled.

The aftertreatment of these patients is important. The hourly feedings and alkaline powders must be continued even after the patient is pursuing his regular occupation. If this is impossible, he may be allowed a light breakfast of from ten to twelve ounces of cereal, eggs, bread and butter, or any soft food. A thermos bottle containing equal parts of cream and milk can be utilized for supplying the hourly feedings. Three or four ounces can be taken hourly until noon, when a light luncheon may be eaten, consisting of easily digestible meats. During the afternoon three or four ounces of milk and cream should be taken hourly until the evening meal. The total bulk of food should not be sufficient to cause a greater increase in weight than is desired. If hourly feedings cannot be maintained, the three usual meals should be substituted and the powders taken every hour for three doses after a light breakfast; one hour after luncheon a powder should be taken, two powders at the end of the second and third hours, and one at the end of the fourth. After ten to twelve weeks the feedings may be increased to two hour intervals and the powders continued midway between the feedings.

About twice the amount of food should be taken at each feeding, and two powders midway between the feedings. At the end of twenty or more weeks the patient may partake of three meals daily and may be allowed a glass of equal parts milk and cream midway between breakfast and luncheon, and between luncheon and dinner; two powders should be given between breakfast and the milk and cream, two between the milk and cream and luncheon. Powders should be taken similarly in the afternoon, and finally two powders three hours after the evening meal. The writers assert that this treatment has given them ninety-four per cent. of cures in the mild cases; eighty-five per cent. in the moderately severe; eighty per cent. in the severe cases, an average of eighty-six per cent. of cures in all cases and the results were better than those obtained by other forms of treatment.

Treatment of Hyperchlorhydria in Children.—James Hoyt Kerley (*Medical Record*, May 8, 1920) describes this condition in children as accompanied by a feeling of fullness in the epigastric region, with indefinite pains radiating from the region of the umbilicus; there are also often eructations of acid gas and heartburn. A powder of magnesium carbonate, one grain, sodium bicarbonate, two grains, and bismuth subcarbonate, two grains, may be given fifteen minutes before each meal. For the constipation rhubarb and soda mixture, combined with aromatic cascara sagrada, may be given in one or two dram doses at bedtime. The diet should be carefully regulated. Orange juice, if allowed, must be taken only after the morning meal; the white of egg only is to be eaten, as the yolk excites acid secretion. Highly seasoned soups should be forbidden, and red meat taken only once a week. All excessive sugar, candy, sodas, ice cream, and pastry are to be avoided, and tea, coffee, and ice water are harmful. Raw fruit is not permitted until the appetite has become normal. A diet of farinaceous foods with milk, potatoes, green vegetables, stewed fruits, with wheat bread, toast or zwieback is to be followed. A proper amount of rest is to be insisted upon, with a change of scene in the worst cases. This condition is a common cause of defective appetite in children.

Early Lesions in the Gallbladder.—William Carpenter MacCarty and J. R. Corkery (*American Journal of the Medical Sciences*, May, 1920) state that the early changes in the gallbladder consist of: 1. Congestion and edema of the villi frequently associated with a bulbous appearance which makes them look cystic; occasionally they are cystic. 2. Local or general slight degree of lymphocytic infiltration, which manifests itself only in a slight enlargement of the villi and a cloudy or duller appearance. 3. Local or general slight degree of lymphocytic infiltration in the mucosa alone, which may be normal, but when seen in association with a similar infiltration in the submucosa, muscularis, and subserosa, probably indicates a pathological condition. 4. The presence of fibrosis in the villi, which usually are not thin and tentacular in sections like those of the perfectly normal organ. The fibrosis sometimes extends into the submucosa, muscularis, and subserosa. 5. The presence of lymphocytic infiltration and fibrosis plus the presence of a finely granular or lipid substance in the epithelium, or just below the epithelium in the mucosa. 6. The presence of slight or no lymphocytic infiltration and fibrosis plus the presence of large spheroidal cells filled with finely granular lipid substance in the mucosa and sometimes in the submucosa. These cells are similar to those which have been described in the so-called strawberry gallbladder, and in papillomas. This substance may not be visible grossly, but may sometimes be detected with the high power dissecting microscope. It is the substance which gives villi in the strawberry gallbladder and papillomas their yellow or white appearance. The conditions described do not alter the gross exterior of the organ, and do not greatly alter the internal appearance to the naked eye. Therefore a careful microscopic examination is required.

Intestinal Complications of Measles.—Giulio Funaioli (*Gazzetta degli Ospedali e delle Cliniche*, December 7, 1919) thinks that these are much more frequent than is ordinarily supposed. He believes that they may be divided into three classes: 1, prodromal; 2, concomitant or primary, and 3, secondary. The primary are due to intestinal enanthemata, while the secondary are due to the normal inhabitants of the bowel. The prodromal are usually due to a preexistent enteritis, as at this time the measles virus could not produce any noteworthy intestinal lesions.

The Effect of Pyloric Obstruction in Relation to Gastric Tetany.—W. G. MacCallum, Joseph Lintz, H. N. Vermilye, T. H. Leggett and E. Boas (*Bulletin of Johns Hopkins Hospital*, January, 1920) produced pyloric obstruction in dogs and found that when the acid gastric juice was all removed and no chlorides were given in the food, spontaneous twitching and usually violent convulsions developed. A constant rapid diminution in the plasma chlorides with a corresponding rise in the alkali reserve was noted, together with a heightened electrical excitability. It was possible to prevent these symptoms by giving the animal a large supply of chlorides following the operation. After the onset of the symptoms the administration of chlorides had a beneficial effect.

Carcinoma of the Duodenum.—According to J. B. Deaver and I. S. Ravdin (*American Journal of the Medical Sciences*, April, 1920) carcinoma of the duodenum is a rare condition found in 0.033 per cent. of hospital autopsies. The percentage of carcinomas of the entire intestinal tract originating in the small intestine varies from 2.5 per cent. to 3.1 per cent. The relative proportion between carcinoma of the duodenum to that of the jejunum and ileum is 47.7 to 52.2 per cent. Inch for inch the duodenum is much more likely to undergo carcinomatous change than the jejunum or ileum. The relative frequency at various sites of duodenal carcinoma is: First portion, 22.15 per cent.; second portion, 65.82 per cent.; third portion, 12.02 per cent. Carcinomatous degeneration of chronic duodenal ulcers is not so frequent as in chronic ulcers.

Dietotherapy in Diseases of the Pelvic Bowel.—Charles J. Drucek (*Western Medical Times*, February, 1920) gives the following plan of a day's menu to serve as an outline, to be modified according to the individual's habits and the seasons:

Breakfast—Fruit (one orange, or a bunch of grapes, half a grapefruit, a baked apple, or a dish of cooked fruit, such as prunes, peaches, apricots); two slices of crisp bacon or two eggs, with two muffins or gems, or slices of toast with butter; or a dish of porridge with cream; and coffee, black or with cream and sugar.

Lunch—A bowl of vegetable soup or puree with crackers; a sandwich, or two rolls with honey; a glass of buttermilk or fermented milk.

Dinner—A bowl of soup; one lamb chop, or a similar sized piece of beef or poultry; two slices of bread; one potato; salad; green vegetables, such as spinach, string beans, asparagus or cauliflower; a dish of pudding of rice, chocolate, gelatine or tapioca with fruit or a fruit sauce.

REPORTS OF UNUSUAL CASES.

With the Anatomical Diagnosis.

BY NELLIS B. FOSTER, M. D.,
New York.

It not infrequently happens that our most obscure cases remain to us a sealed book, because of the absence of a postmortem examination. On account of the autopsy records the following cases of unusual or rare diseases may be of interest.

CASE I.—The patient was a young man twenty-four years old, who came to the hospital on account of what he termed severe indigestion. He stated that he had always had more or less trouble with his stomach and had had to be careful about what he ate, and he was subject, at irregular intervals, to attacks of abdominal pain accompanied by nausea. The pain had been in the upper part of the abdomen usually, and with these attacks he felt nauseated, but did not usually vomit. He had consulted several physicians, who had regarded the condition as due to chronic appendicitis. The particular attack for which he came to the hospital was similar to other attacks that he had had. It began rather suddenly during the forenoon and was ushered in by abdominal cramps. These pains had increased in intensity, so that he gave up work and went to his room and later came to the hospital. He had been nauseated and had felt like vomiting, but had not done so. When examined he was found to be bordering upon collapse. He was a thin, poorly nourished man, who appeared very ill. The temperature was normal and the patient was bathed in a cold sweat. He localized the pain in the left upper portion of the abdomen. The examination revealed a tympanic note over the left chest, extending to the fifth rib in the axillary line. Over this area the breath sounds could not be heard. The admission diagnosis was pneumothorax based upon these findings. Examined in the ward by one of our staff, the scaphoid appearance of the abdomen and the confirmation of these physical signs suggested to him the possibility of a diaphragmatic hernia. The condition of the patient excluded the employment of any methods of confirming this. The patient did not rally, but died within twenty-four hours after admission to the hospital.

The anatomical diagnosis was diaphragmatic hernia, congenital; the stomach and small intestine were in the left thoracic cavity, the displacement causing a volvulus in the mid portion of the ileum and secondary gangrene of two feet of intestine.

Diaphragmatic hernia, although uncommon, is not excessively rare. The clinical history given by this patient is the usual one, in that repeated attacks of abdominal pain associated with digestive disturbance and vomiting are characteristic. Apparently, viscera may pass in and out of the thoracic cavity under these circumstances, resembling in this respect the spontaneous reduction of usual hernias, inguinal for example, and it is not until strangulation occurs, due often to volvulus and occlusion of the blood supply, that serious symptoms arise. If seen early the diagnosis may be confirmed by radiological examination. The condition is not necessarily fatal, a number of patients having been operated upon successfully and the hernia closed.

CASE II.—A young Italian, twenty-three years of age, was admitted to the clinic complaining of precordial pain, cough, hoarseness, dyspnea and difficulty in swallowing. The history was quite negative up to the onset of the symptoms for which he came to the hospital. Two weeks prior to this time he had begun to have pain in the upper part of his chest, especially on the left side, and about this time he began to be short of breath and have some cough. The hoarseness and difficulty in swallowing developed later. During the taking of the history the patient had several paroxysms of coughing which were characterized by the ward surgeon as "typically brassy."

The patient was a stockily built Italian, with some cyanosis of the face. There was definite, visible pulsation over the upper portion of the sternum, which did not extend into the cardiac region. Dulness could be outlined an inch and a half to the right of the sternum in the second and third costal spaces, and there was a definite heave over this region on palpation. There seemed no question with regard to the diagnosis; all signs and every test pointing to an aneurysm of the arch of the aorta. There was a distinct difference in the blood pressure in the two brachial arteries. Examination of the vocal cords indicated probable impingement of the recurrent laryngeal nerve. The fluoroscopic examination showed a pulsating tumor in the upper mediastinum and the Wassermann reaction was four plus. The patient's downward course was very rapid and death took place from aspiration pneumonia.

The postmortem examination disclosed an aneurysm, as we had suspected, not of the aorta, but of the pulmonary artery. Aneurysms of the pulmonary artery are very rare, there being only a few

reported in the literature. Differential diagnosis is almost impossible to establish, since pulmonary signs which might be supposed to develop are as a matter of fact not infrequently noted with thoracic aneurysms on account of pressure.

CASE III.—Septicemia taking origin in the genitourinary tract. This patient contracted urethritis the latter part of May and was given local treatments, the nature of which are not known further than that they were quite painful. On the fifth of June abdominal pain developed, with nausea and chilly sensations, and he remained at home from his work. The following day, June 6th, he had diarrhea and severe burning on urination. The high temperature continued and he felt so sick that he came to the hospital. On admission to the hospital he had a temperature of 103.6 degrees, appeared very uncomfortable and was slightly delirious. The following day, June 7th, it was noted at the morning examination that the patient was drowsy and that there was a slight ptosis of the right eyelid, the right pupil being larger than the left, and some drooping of the right corner of the mouth. The reflexes were all present but sluggish. No muscular weakness could be determined at this time, nor changes in sensation.

At the afternoon rounds it was noticed that the left leg was definitely weaker than the right and that there were scattered over the body, a few purpuric spots. The eyegrounds were normal. Lumbar puncture was done. The spinal fluid containing 150 cells to the c. mm. A blood culture had been done earlier in the day. A diagnosis was made of a primary urethritis, acute posterior urethritis and prostatitis, septicemia, multiple emboli in the central nervous system and meningitis.

The anatomical diagnosis at autopsy was acute posterior urethritis, acute prostatitis, thrombosis in the prostatic veins, acute vegetative endocarditis of the aortic valve, multiple cerebral emboli, multiple mycotic abscesses (kidney, spleen, liver). The blood cultures showed *Streptococcus hemolyticus*.

CASE IV.—This patient came to the hospital on account of an inguinal adenitis, following a urethritis which had not been treated. The nodes in the right groin were large and fluctuating with considerable local reaction. Following free incision, the patient did well for two days. On the third day, consultation was sought of the medical division on account of considerable rise in temperature, pain in the left chest and cough. It was suspected that pneumonia might have developed. Examination showed that there was undoubtedly fluid in the left chest and exploratory puncture demonstrated this to be pus. The inguinal wound looked clean. The heart appeared to be dilated, but there was no evidence of an endocarditis. There was some debate as to the best therapeutic procedure, opinion being divided as to the necessity of immediate thoracotomy. The smear from the pus in the pleural cavity showed chains of cocci, probably streptococci. The patient was operated upon for empyema and died within twenty-four hours.

The anatomical diagnosis was posterior urethritis, acute prostatitis, thrombosis of the prostatic plexus,

multiple abscesses involving liver, spleen, kidneys and lungs, acute suppurative pleurisy (right), acute suppurative pericarditis. The blood cultures reported after death showed *Streptococcus hemolyticus*.

Generalized blood infections as a sequel to acute posterior urethritis are rather more common than is generally supposed. Two factors stand out as predisposing, namely, excessive vigor in the earlier stages of treatment and the second factor is neglect of all treatment. Genitourinary surgeons appreciate, more than internists are likely to, the important part played by secondary infections in urethritis; indeed the late complications are likely to be due to streptococci rather than to gonococci.

CASE V.—The patient was a woman forty-two years of age, who was admitted to the ophthalmological service on account of rapidly failing vision. Her history was that she had always enjoyed good health, until about six weeks before admission to the hospital. At that time she began to have bleeding of the gums and this had continued intermittently up to the time of admission. The bleeding was not associated with any soreness, but had been persistent and she thought she had lost a good deal of blood and, of course, the bleeding had interfered with the taking of food, because it destroyed her appetite. About ten days before admission to the hospital she had noticed that her vision was somewhat dim. Since then her eyesight had failed steadily until she was unable to distinguish any object, in fact could only see sufficiently to distinguish light from dark. The ophthalmological examination revealed a bilateral optic neuritis of a severe degree. There had been at no time headaches, nor any focal symptoms suggesting implication of other cranial nerves; no symptoms of any kind in fact, except the bleeding gums and gradually failing vision.

The examination was wholly negative. The gums were somewhat spongy and were exuding blood constantly. The blood count was normal. The coagulation time of the blood was normal. The patient was removed to the medical side for further observation. A few days after the transfer signs developed indicating fluid in the right chest. This fluid was withdrawn. It was clear and had the characteristics, chemically and cytologically, of a transudate. Only one abnormal feature was noted in the pleural fluid. In our hunt for a clue to explain the peculiar condition we did everything that was suggested to us and, among other things, the albumin globulin ratio was estimated. The globulin was considerably increased, and to this we attached a significance which was not justified by subsequent disclosures. Repeated examinations of the blood failed to detect anything except severe secondary anemia. In the meantime it was evident that the patient was losing ground on account of the persistent bleeding from the gums and it was felt by the dental consultant that this could be checked only by removing the teeth. Following the removal of the first two teeth the hemorrhage was so persistent that the patient nearly died. Several weeks later we prepared for the second dental operation by transfusing the patient. By stages in this way all of the teeth were eventually removed. The bleeding of

the gums ceased; the vision gradually returned. The fluid in the pleural cavity required aspiration on two separate occasions, after which it ceased to reaccumulate. The whole period of treatment in the hospital covered about four months.

When the patient left the hospital she appeared in good health. Her eyesight, while not normal, was very good and she could read without serious difficulty. There had been no return of the bleeding of the gums or of loss of blood elsewhere. There was, however, very little change notable in the ophthalmological examination.

The patient returned home and remained there for two months apparently improving constantly. Then, rather suddenly, she began to have shortness of breath, which rapidly increased in severity, on account of which she was brought back to the hospital. It was found, at this time, that both pleural cavities contained considerable liquid and aspiration showed that this liquid was deeply blood tinged, so much so that a blood count was made, and it was found that the fluid contained about a million red cells to the c. mm. On the strength of this, the diagnosis of neoplasm was made, the nature and location of which could not be determined. This was not the first suggestion of a neoplastic origin for the symptoms, one of the members of the staff having expressed the opinion that the peculiar atypical symptoms were best explained by the hypothesis of chloroma. Following removal of fluid from one chest there was rapid reaccumulation. The patient failed rapidly and died the second day after admission to the hospital. The diagnosis was chloroma.

Chloroma is a peculiar and rare malignant disease, primary in the bone marrow and giving rise to metastatic growths, chiefly in the skull, orbit, sinuses, and mediastinal lymph nodes, found also quite often in the sternum, vertebræ and occasionally in the long bones. The earliest symptom in many cases has been exophthalmus, less commonly the earliest symptom is blindness or deafness. Hemorrhages do occur, although they are not usual. Various blood pictures have been described and two main classifications have been pointed out, lymphemia and myeloma, but not infrequently leucocytic increase is absent; in other words, there are leucemic and aleucemic chloromas. Certain peculiar cells have been noted in the circulating blood in some cases and these chloroma cells were for a time regarded as diagnostic, but this opinion is no longer held. The axillary or inguinal nodes are sometimes enlarged. In brief, chloroma represents a leucemic process of a definite neoplastic type.

CASE VI.—The patient was a young man who consulted us on account of a sense of compression in the chest and dyspnea. He stated that he had always been in good health; had had no sickness of any importance that he could recall. Two weeks prior to consultation he was injured while playing football, but this injury at the time was regarded as a trivial matter, and he thought nothing of it for several days, when he began to be troubled by a sense of oppression and slight shortness of breath. On examination the signs presented were those of liquid in the left chest, with displacement of the

heart to the right. It was supposed at this time that the case represented the ordinary type of pleurisy with effusion, probably of tuberculous origin. The chest was aspirated and the cell count on the fluid was eighty-four per cent. lymphocytes. The patient ran a fever course after the first few days, his temperature ranging between 97° and 102°, with afebrile periods of ten days or two weeks' duration. The fluid rapidly accumulated after aspiration and paracentesis was repeatedly necessary in order to keep the patient comfortable. In all he was aspirated thirty-four times and forty-two litres of fluid were withdrawn. The fluid was never blood tinged. The prompt reaccumulation of fluid after the earlier aspirations led to a revision of the diagnosis to endothelioma of the pleura.

At autopsy the condition was found to be primary sarcoma of the pericardium, with extension to the pleura and metastases in the mediastinal lymph nodes, likewise those of the peritoneum.

CASE VII.—The first patient was brought to the hospital suffering from apparently a slight infection ("P. U. O."). There was a slight rise in temperature which had come on a few hours before, slight abdominal pain and some vomiting. On examination the patient presented no signs, other than a moderate degree of tympanitis. Especial care was given to examination of the lungs on account of the tympanitis, suspecting that pneumonia might be the underlying disorder. The condition of the patient rapidly grew worse, the pulse became thready, the blood pressure fell and in twenty-four hours after he entered the hospital he was in a collapse and comatose. He died during the second day.

At autopsy no lesion of any sort was discovered, excepting in the adrenal glands. The architecture of these was practically destroyed by numerous hemorrhages which appeared to be recent. The blood cultures which had been made before death yielded a diphtheroid organism. The pathological diagnosis was hemorrhagic suprarenitis.

It is an old clinical adage that rare diseases come in pairs. Our first case of suprarenitis was not recognized before death. The second patient came in with the same history of sudden onset of fever, slight abdominal pain and vomiting. The examination revealed only tympanitis. A few hours after he was admitted to the hospital he had a series of convulsive seizures, which were followed by collapse. The hazardous diagnosis of hemorrhagic suprarenitis was made, because of the similarity of the clinical picture to our first case. The autopsy established the correctness of the conjecture.

Hemorrhages into the adrenals have been described with a number of infectious diseases and I noted them quite frequently during the influenza epidemic at a military hospital. Isolated cases of hemorrhagic suprarenitis must be regarded as a local manifestation of an overwhelming infection. The characteristic features are the onset, resembling the period of invasion of any infection, the rapid downward course, the tympanitis, occasionally convulsions and purpura. Death usually occurs within forty-eight hours.

121 EAST SIXTY-SECOND STREET.

OBSERVATIONS ON THE STIGMATA OF
DEGENERATION AS FOUND IN
THE FEEBLEMINDED.

BY MARTIN W. BARR, M. D.,

Elwyn, Pa.,

Chief Physician, Pennsylvania Training School for Feeble-minded
Children.

"A fellow by the hand of Nature mark'd."

King John, iv., 2.

That stigmata are not only present, but prove a valuable aid in the diagnosis of mental defect, there can be no doubt. But one cannot point to any single deviation from the normal and say positively that it alone is peculiar to any special defect. It is equally true that many perfectly normal people may exhibit some stigmata; but never in such combinations as do defectives. Thus a single anomaly in an individual is not indicative of degeneration; but a combination of three or more will naturally lead the investigator to look for associated mental or moral defects, as in accordance with the now accepted theory, the individual exhibiting from three to five stigmata should be classed as defective beyond a peradventure.

According to Dana two per cent. of normal males present some deviation; while thirty per cent. of the neurasthenics, insane and criminals exhibit deviations and many anomalies are found among the feeble-minded. Perfect mental and physical development usually accord, the intelligence having a decided influence in shaping the head, limbs and trunk.

In many cases there is moral without mental defect; indeed the former may be so marked as to completely overshadow mediocre intelligence. Suetonius's description of *The Twelve Cæsars* is a running commentary of moral without mental degeneration.

In the observation and careful study of mental defectives covering a period of thirty-three years, numbering many hundreds of boys of all grades, I found in each and all innumerable anomalies and in not one case were these absent. Without going into percentages, which are likely to prove tiresome, I briefly note some of the principal stigmata of degeneration found among the feeble-minded:

Many exhibit, superficially, a good physique, but there is almost always a lack of strength, and they tire easily and succumb readily to disease. As a class the feeble-minded are undersized, noticeably the idiots, Mongolians and microcephalics, but some of the brighter ones show increasing growth through the middle grade up to highest, where in many cases they may be normal in height; the acromegalics may reach seven feet—or indeed even more.

There is almost invariably a lack of congruence between the appearance, and the actual or chronological age. Before the age of forty the patients appear much younger; but after attaining this age (which but few of them do, the actual life of a mental defective being from twenty to twenty-five years) they exhibit signs of rapid decay. Not infrequently there is faulty or deficient innervation of the different muscles and hyperhidrosis is common. The hands and feet are in many cases cold and

clammy, especially among those of the low and middle grade.

THE HEAD.

The head exhibits many peculiarities in regard to shape. In addition to the extremes of microcephaly and hydrocephalus there are, in its many asymmetries, frequent deviations from the normal; this is especially noticeable among the low grades. (Note.—The term low grade refers to the imbecile of that type; when the plural is used it includes not only the low grade imbecile but also the idiocretin and idiot.) According to Peterson (1), all length breadth indices between seventy degrees and ninety degrees may be considered as physiological deviations.

The cephalic indices range from seventy degrees to ninety degrees, and the largest number in all grades is eighty degrees; therefore most mental defectives are mesocephalic. The cephalic indices in accentuated cases of mental defect are: Mongolians from seventy-six degrees to ninety degrees, the most common being from eighty-five degrees to eighty-eight degrees, this class being for the most part brachycephalic; acromegaly seventy-three degrees, dolichocephalic; dementia præcox from seventy-two degrees to eighty-five degrees, the most common being eighty degrees, therefore mesocephalic; microcephals from seventy-two degrees to eighty-nine degrees, the most common eighty-two degrees, brachycephalic; moral imbeciles from seventy-three degrees to eighty-five degrees, eighty-five degrees being most frequently found, and, therefore, they also are brachycephalic.

Except in a very few cases the length and maximum width of the skull varies but little in the different grades. The longest faces are found most frequently first among middle grade imbeciles, next among the high and last among the low grades. Unusually wide faces are equal in the high and middle grade, and least frequent among the low grades. The nasobregmatic arc is most pronounced in the high grade, next in the middle and then in the low grade. The craniofacial angle is about eighty degrees in the middle and high grade, and sixty-nine degrees in the lower grades, including idiots and idiocretins. Prognathism is most common in the low grades, and opisthognathism and orthognathism in the middle and high grade. Facial asymmetries are found most frequently on the right side in the high grade, and on the left side in the middle and low grades, including idiots and idiocretins. Squints and tics are about equally distributed in the various grades except in the Mongolian idiots where they preponderate. Depressions over the glabella are equally divided in all grades and are most frequently found among epileptics. The lemurian hypothesis is rather rare but when found is equally divided among all grades. Thick, coarse lips predominate in the low grades—and are found next in middle, and least frequently in the high grade. Fissured lips occur most frequently in the high grade, then in the middle and last in the low grade. Harelip, which is extremely rare, is practically confined to the high grade; and is almost never seen below the middle grade. Perléché is common in the middle and low grades.

THE TEETH AND PALATE.

The largest number of decayed teeth are found among the low grade and idiots; this of course for obvious reasons. Peculiar and badly formed teeth (especially the abnormal length of the canines) are confined to low grades. The notched or furrowed teeth (Hutchinson's teeth) are due to inherited syphilis, and are common to all grades; as are the rachitic teeth, and also the continued presence of milk teeth. The V shaped palate is found most frequently in the high grade, next in the low, and in the middle least of all. The semi V is found in high and low alike; the saddle is most frequent in the high, then middle and then low. Cleft palate is rather rare, but is evenly distributed between the high and low grades. Asymmetries of the hard palate are in predominance on the right side in the high and middle grade, and in the low grades they are found both right and left. The uvula, often short, twists to the right most frequently in the high grade; in the middle and low grades the twist to the left predominates. The torus palatinus is commonly seen in the low grades, next in the high, but is rarely found in the middle grade.

The tongue is noticeably large and thick, and often protruded from the lips of the low grades, markedly so in the cretinoids, Mongolians and microcephals, among whom it is almost invariably fissured deeply with greatly enlarged papillæ. The tongue among the low grades is likely to be square, but among the high and middle grade is pointed. Broad noses are found most frequently in the middle and low grades; while long narrow noses predominate in the high grade. Asymmetries of the nose are most frequent on the right side in all grades; as are deflected septums.

THE EYE.

The eye is the seat of many deviations from the normal. In the moral imbeciles we find the red glint, hard look, and fleeting shifty expression, which is almost impossible to describe. In the low and middle grade strabismus is not uncommon; and in the Mongolian type there are the oblique eyelids peculiar to this class. Visual defects are very common in all grades. Not infrequently there is marked asymmetry of the eyes in middle and low grade; but most common in the low. Nystagmus is found in the high and middle grade. Photophobia is frequent among idiots and low grade imbeciles; and congenital cataract is rather common in all grades.

The thyroid gland is rudimentary or altogether absent in cretins; and in the Mongolians its development is frequently arrested. Goitre is not very common but when present is found in all grades of mental defect.

THE EAR.

The external ear shows a greater number of anomalies than any other organ. Blainville's ear is common to every grade. The concha is largest in the high grade, and sometimes reaches enormous size in the moral imbeciles; and exhibits rudimentary or arrested development in the middle grade. The relation of the concha varies, the left being usually higher in the high grade. Arrested development of the helix is found most often in the

high, especially in moral imbeciles; next in middle and least in the low grades. Excessive development is seen most frequently in middle, then in the low and last in high grade. The open helix occurs first in the high, next in the low and last in the middle grade. Double helix is evenly distributed among all grades. Darwin's tubercles are common, and are found most frequently among the high grade, on the left side of the middle third of the helix; in the upper third they are not so frequent; in some cases they are seen on both ears. In the middle and lower grades they are about equally distributed between the middle and lower third. The antihelix is excessive in high, next in middle and least in the low grades. The tragus is excessive in middle and high grade; and in the latter is very frequently double, especially in the moral imbeciles. When arrested it is confined almost exclusively to the middle grade. The antitragus when either excessive or rudimentary is found in the high grade, especially in the moral imbecile. Double hematoma is found in middle grade; and when single is confined almost exclusively to the left ear. The lobules are most frequently adherent in the middle grade; and next in the high, and sometimes they are entirely absent (Wildermuth's Aztec ear), rudimentary or extremely broad. The long lobule is peculiar to the low grades. Morel's ear is quite evenly distributed in all grades.

THE SKIN.

The skin, while usually of fine texture and normal color in the high grade, deteriorates in the descending scale of intelligence. In the cretins and Mongolians it is pallid or sallow and leathery, and in many cases prematurely wrinkled. Occasionally among the low grade imbeciles and idiots there are brachial clefts, preaural sinuses and nævi of varying size, or areas of pigmentation. In the high and middle grade, there are scars, most frequent among epileptics, due to their numerous falls during paroxysms. In these grades also is seen tattooing (especially among the moral imbeciles), the designs, often of women, being mostly obscene in character; although somewhat favorite devices are hearts and gravestones inscribed with mother, or the names of other loved ones. Mental defectives of every grade are prone to acquire skin diseases, especially the various eczemas.

It may be of passing interest to note that, while not a stigmata of degeneration, blondes and brunettes are fairly evenly divided among the various grades, the former predominating slightly in the high grade, and the latter in the middle and low grades. Brown and gray eyes are found in all grades—the largest number in the middle. Black eyes are noted most frequently among the high grade and blue among the low grade.

THE HAIR.

Black hair is distributed equally through all grades. While yellow and red hair are most common among the middle grade, red hair is almost never seen among the low grades. In the high grade brown hair is most frequent, as also in the low grades. The beard is usually heavy in all grades, and in the middle and low grades it is very

coarse; but in some cases there is absence of beard. The eyebrows frequently meet and may be heavy and bushy in the high and middle grade; while in the low grades they are scanty or absent. In many of the high and middle grade there is a lack of hair on the body; but not infrequently in the low grades tufts of coarse hair are found in the sacrolumbar region, and on the abdomen.

In three cases I have seen a heavy growth of coarse, curly, black hair, enveloping the body like a jacket. The pubic hair in all grades is usually very heavy and thick; but occasionally in the low grades it is altogether absent. In cases of dementia præcox and microcephaly I find an absence of hair on the chest; which according to Lanceraux is indicative of a tendency to tuberculosis. This I have seen verified in a number of cases. In the middle and low grades there are sometimes congenital spots of baldness; and hairy moles on face and trunk; and patches of gray hair may appear in very early life.

THE EXTREMITIES.

The arms are found to be asymmetrical first in the middle, and next in the low grades; especially the Mongolians. Hands are largest in the middle grade; and are asymmetrical in all grades. The cretins and Mongolians invariably have short clubbed fingers. Polydactylism and webbed fingers are rather rare, and are confined to the low grade and idiots for the most part. Left handedness is also rare, and confined almost exclusively to the middle grade. Occasionally the high grade are ambidextrous, especially the moral imbecile.

The legs, asymmetrical, are longest and shortest in the middle grade. Small feet are found most frequently in the low grade; and next in the high. Large feet are seen often in middle grade, and also in low. Flat feet are very common in the middle grade, and in Mongolians. High instep is found highest in high grade, and lowest in low grade. The various talipes are found to some extent among all grades, especially talipes planus, as are hammer toes.

Funnel breast, *thorax en entonnoir*, is found in the lower grades, especially the Mongolian; and *pectus carinatum* or pigeon breast among all grades; but most often among the middle and low.

The kyphotic pelvis is seen almost exclusively among the lower grades, as is the scoliotic pelvis; and the elongation of the coccyx, suggestive of the stump of a tail, is found among the lower grades, especially the idiots.

Heavy, thickened, pigmented nails are very common among the middle and lower grades, and many have flat furrows extending the entire length, giving a rough appearance. When heavily ridged—generally transverse—they are called neurotic nails, and are frequently found among the high grade. Many are addicted to onychophagy, or biting of the nails. This occurs to some extent among the middle and high grade, but rarely among the low grades.

The male generative organs are worthy of attention as exhibiting marked deviations from normal. In all grades the penis is greatly enlarged both in length and circumference. Phimosis is the rule, and not the exception in all grades, as are

epispadias, hypospadias, and cryptorchism. Masturbation is common in every grade, even the profound idiot. Aspermia, and azoospermia are found mostly among epileptics of all grades. There is retarded genital function, as well as sexual desire, and loss of sexual power, in all grades; but when roused there is excessive exaggeration which in many cases exceeds all bounds often amounting to satyriasis. Atrophy of the sexual organs is not very common. In rare cases there is so-called hermaphroditism among the high grade, especially the moral imbecile.

Defective vision, hearing, taste and smell, as well as anosmia are found most frequently in the middle and low grades, especially the latter. Defective hearts are found in all grades, but most frequently among the middle and low; especially are they to be noted among the Mongolians and microcephals. Mitral and aortic regurgitation are common, as is tachycardia. Hemophilia, or uncontrollable bleeding, is occasionally encountered in the middle grade. Mirror writing is not infrequently seen, and always in the high grade. Many, especially among the low grades, are insensitive to pain, and will take great delight in watching the setting of a broken bone or the amputation of their own fingers.

Speech is retarded in all grades. Stammering occurs mostly among the high, and next among the middle grade; while among the low grades it is rare. There is defective articulation among all grades, but it is most pronounced among the low. Burring and lisping occurs among the high and middle grade, but almost never among the low grades. Semimutism and mutism are found principally among the middle and low grades. Weak digestion is rare; and all grades are gormandizers and are likely to overeat. Constipation is common in all grades, but markedly so in the low, in which it may alternate with diarrhea; and many are persistently unclean both night and day. In a large number of cases, in all grades, there is both retarded dentition and locomotion; and they are much slower in learning to dress and undress than normal children; and are awkward in the use of their hands; and lack of prehension, as well as poor station may be noted, especially among the middle and low grades. Epilepsy and chorea are common in all grades.

The high and middle grades are sometimes diffident in meeting strangers; but as a rule they are egotistical, and are so fond of attracting attention that they will go to almost any length, even resorting to selfmutilation. The moral stigmata are always prominent, and in many cases exceed the physical. The high grade, and especially the moral imbecile, are veritable artists in crime, and usually brutal and cruel, and always crafty and cunning, deceitful and untruthful; mendacity amounts almost to an art, their lies being simply wonderful.

There is a lack of true affection; and gratitude among the mentally defective is by no means a lasting quality. They are all adroit thieves, and are extremely cunning in gaining their ends; but as they have little acquisitiveness, and only a very limited appreciation of relative values, they will steal for no reason whatsoever except the excitement. As a rule they are not revengeful, but are

generous and kindhearted to a degree; their emotions are easily stirred; and they are lazy and sluggish in habits. In sexual perverts a mincing gait is noticeable, and feminine appearance and actions; and there is a peculiar shuffling walk among the lower grades which is often a mere lurching forward. All grades have phenomenal memories for peculiar things—dates and unimportant events, but the residual or practical memory is almost always very deficient.

The following deviations from normal, common to all grades of the feeble-minded, occur so rarely that I call attention to them simply as a matter of record; although when present, especially in combination, they are indisputable indications of degeneration.

The head.—Cephalones without hydrocephalus; trigonocephalus, oxycephalus, plagiocephalus, sphenoccephalus, trochocephalus, leptoccephalus, platycephalus.

The eye.—Megalophthalmus, microphthalmus, microphepharon, symblepharon, colomba palpebræ, coloboma iridis, coloboma choroideæ, congenital; coloboma lentis, congenital; epicanthus, aniridia, polykoria, corectopia, staphyloma posticum scarpal, arteria hyaloidea, retinitis pigmentosa, hemeralopia, daltonism, acrometropsia, nyctalopia, dermoid adhesions on cornea.

The ears.—Stahl's ears No. 1—No. 2—No. 3; faunonian or satanic or pointed ear.

Thorax.—Gynecomastia or excessive development of breasts.

The extremities.—Defective extension of fingers; excessively long hands and fingers; great strength and abnormal development of left hand and leg; congenital luxations, aplasia of extremities, hypoplasia of extremities, micromelus, apus and abrachius, peropus and perobrachius, ametus, phocomelus, perometus, sympus apus and sympus opus, monobrachius and monopus, achinus and perochirus.

THE TYPES OF CARBONATED BRINE BATHS (NAUHEIM).

A Discussion of Their Comparative Values.

By N. PHILIP NORMAN, M. D.,
New York,

Late Major, Medical Corps, U. S. Army.

In 1857 Beneke observed that carbonated brine baths had a very decided effect in influencing the course of diseases of the heart and circulatory apparatus. This was contrary to the current opinions held by the medical profession at large and the physicians practising at Bad Nauheim. Prior to Beneke's observations, which he subsequently proved, the carbonated brine bath was held to be dangerous to heart patients. However, the treatment had been occasionally risked on a few patients with heart disease when the rheumatism of which they chiefly complained was so painful that relief was imperative, despite the possibility of the traditional hazard of life involved in the therapeutic effort. Beneke

was not tardy in recognizing that the beneficial effect of the baths in these few cases was due not alone to the effect upon the rheumatic condition, but to a great extent to the general tonic effect upon the heart and circulation which indirectly influenced the rheumatic condition.

This briefly outlines the history of the development of carbonated brine baths as a therapeutic agent for cardiovascular renal diseases. The method has been developed and scientifically elaborated by such men as the Schotts and the Groedels in Germany, and by Baruch in this country. From the time that Nauheim became recognized by the profession as the Mecca for heart patients, attempts have been made to duplicate this bath by two classes of individuals, physicians and laymen, with two definite purposes in view. Physicians have labored to develop the artificial bath that their patients might have the advantages of this form of therapy without incurring the expense of a trip to Nauheim or without necessitating the complete separation of themselves from their domestic and community relations.

The other set of individuals, composed of laymen, have followed in the development of the artificial bath, not actuated so much by the scientific enthusiasm of the therapist but rather with the purpose of profiting financially from this therapeutic venture calculated to interest the hundreds of heart patients in this country by methods of commercial advertising at once insidious in its suggestions and ambiguous in its promise of benefit. An avenue of publicity is sought that is contemplated to reach and attract the public eye rather than the discriminating judgment of the profession through the popular magazines. An ethical way is offered to reach the profession directly, and the public indirectly, by the publication of scientific observations through the pages of the current medical journals. If as much money was spent on developing the scientific methods in vogue for diagnostic and therapeutic purposes as for commercial publicity the return on the investment within a few years would be proportionally commensurate to the thoroughness of the work accomplished.

Because of the claims and counterclaims that physicians constantly hear concerning this and that kind of Nauheim bath this article has been written in an endeavor to classify properly the various types of baths in existence and to evaluate comparatively the merits of each.

Carbonated brine baths (Nauheim baths) are divided into three kinds, as follows:

1. The natural carbonated brine bath.
2. The partially natural carbonated brine bath.
 - a. Using natural carbonated water and artificially prepared brine.
 - b. Using a natural brine water in which the carbonation is artificially prepared.
3. The artificially carbonated brine bath.

Type 1 is to be found only at Nauheim and is the ideal bath.

Type 2, a, as a bath, *per se*, is on a par with Nauheim, as it possesses the most important constituent part of the carbonated brine bath in its natural form of occurrence. It is a matter of common knowledge that the proper physiological action of the bath is

directly dependent upon the efficacy of the carbonic acid gas saturation throughout the brine water. In a natural carbonated brine bath or in a partially natural carbonated brine bath in which the carbonation is natural and the brine artificial, there is such an ideal distribution of the carbonic acid gas throughout the water as to permit the gas bubbles properly to insulate the immersed skin area against a too rapid dissipation of body heat and to stimulate the skin with a thermic stimulus of heat imparted by the gas bubble because of the difference of the point of thermic comfort between that of carbonic acid gas and the water of the bath. In a bath in which the carbonation is natural there are successive crops of gas bubbles that adhere to the skin and provide for a fresh insulation of the immersed skin and facilitate more adequately the physiological action of the gas bubbles than in the bath in which the carbonation is artificial.

Type 2, b, is on a par with the artificial bath. The carbonation is artificial and it is obvious that since the most important physiological factor of this bath and of the artificial bath are the same, that the therapeutic merit must necessarily be equal. Claims have been made that the natural brine was distinctly advantageous over the artificial brine, but the observations of others, as well as my own, have failed to substantiate this clinically. Assuming a proper proportion of calcium and sodium chloride in solution for each bath there is no reason known that confirms the claim of superiority of natural brine water over artificially prepared brine water. Therefore, any claim of this sort is to be discounted. It is merely a connivance calculated to associate in the mind of the reader a similarity of this natural brine water to the natural carbonated brine water of Bad Nauheim. The reader, unlearned in hydrotherapeutic lore, is misled by the mental processes of logical reasoning sequence to ascribe inferentially to this natural brine water an equivalent value to that of the natural carbonated brine water of Nauheim, which does not exist.

Type 3 is the artificial bath and is the equal of Type 2, b. This is borne out by clinical results.

Summing up, it would appear that Bad Nauheim, in point of the bath alone, has distinct advantages that have not been exactly duplicated but are capable of duplication at Saratoga, N. Y. The bath of Saratoga Springs, N. Y., represents Type 2, and when the "method" has been more scientifically elaborated should equal Nauheim as a heart cure. It has no rival in this country in point of natural assets as a heart cure.

However, at this point it is well to call attention to a handicap existing at Saratoga for heart patients. This handicap is the laxative mineral waters. Laxative mineral waters have been used for years in cardinals, based upon a time honored but time worn idea, "elimination." The unprescribed use and abuse of laxative waters by cardiac patients is dangerous, and it is to be hoped that Saratoga will ever exert a restraining influence over the personal inclination of the heart patients to indulge while being treated there.

Type 2, b, having no advantages over the arti-

cial or Type 3 bath deserves discussion in association with the artificial bath. These baths are capable of benefitting cardiovascular renal disease, and while they are not as valuable, *per se*, as Type 1 and Type 2, a, they are nevertheless worthy substitutes.

There are a few places in this country where a brine water similar to Bad Nauheim's is to be found. It is to be hoped that in the event of the development of health resorts at these sites that it will not be because of this natural brine, but because of a conscientious attempt to establish a substitute for those patients unable to journey to Nauheim. The natural brine possesses no inherent advantages for the carbonated brine bath. That it renders the administration of baths less troublesome and less expensive than artificially prepared brine is quite obvious. The profession, I am sure, would gladly support an establishment whose prime interest was directed at the aggressive development of a health resort for heart patients. If a scientific equipment of such an establishment was kept abreast of modern medical progress there would be no need for worry about its financial success. However, the profession cannot be pledged to support an establishment whose atmosphere scents more strongly of commercial interest than of scientific progressiveness.

I have attempted to classify the types of carbonated brine baths (Nauheim baths) in use, basing this classification upon the results of recent advances made in this form of therapy as well as upon personal observations extending over a period of six years. It is my desire to give to those of the profession unfamiliar with this therapy a correct impression of the comparative merit of the different types of baths, so that they may wisely counsel their heart patients as to the advantages of this treatment as well as to advise correctly some despairing patient who may have become enthusiastically confused by advertisements craftily designed to attract his interest by inferential statements which are so indeterminate of tangible fact as to lead him to question the accuracy of his conclusions. If this has been accomplished I shall indeed be repaid for my efforts.

109 EAST SIXTY-FIRST STREET.

THE RESULTS OF OPERATION IN GASTRIC AND DUODENAL ULCERS.*

By GEORGE WOOLSEY, M. D., F.A.C.S.,
New York.

The following study of the results of operation in gastric and duodenal ulcer is based upon 109 cases in which I operated, mostly during the last five or six years, up to December, 1919. This does not include acute perforating ulcers. A few of these 109 cases, principally those of gastric ulcer for which a gastroenterostomy or an excision was done, date further back, but are included for a comparison of the results, as I have done relatively few operations of these types for gastric ulcer in recent years.

*Read before the Surgical Section of the New York Academy of Medicine, May 7, 1920.

Seventy-nine of these operations have been done since January, 1916, at which date the followup system was inaugurated in the second surgical division of Bellevue Hospital. Only one of these was done in 1918, so that the period covered by this group was three years. I have succeeded in getting return or late records in seventy-six of these cases, sixty-two of the operations having been performed since January, 1916. The time after operation of these return records varies from about three months to 110 months, and averages 16.4 months. Those patients who had no gastric symptoms were classed as excellent; those having occasional vague symptoms, not those of ulcer, were classed as satisfactory. The remaining class of unsatisfactory results included those patients who complained of considerable abdominal discomfort, though it was rarely suggestive of ulcer and probably depended for the most part on adhesions and other extragastric causes. There were seven post-operative deaths, five in the period since January, 1916.

Naturally the largest group was that of duodenal ulcer, of which there were fifty-eight cases, but this was only a little over fifty per cent., a low ratio considering the average run of duodenal compared with gastric ulcers. Two of these patients died after operation, one of pulmonary embolism and one of heat prostration, a mortality of 3.4 per cent. The heat prostration would have been prevented had we recognized how hot it was; it occurred at the beginning of an intensely hot spell. Of the remaining fifty-six cases I have return records of forty-five. A number of these patients have come back to the return clinic several times, or I have seen or heard from them repeatedly.

The immediate results, or the condition on leaving the hospital, was excellent in seventy-five per cent. of the cases; satisfactory in 15.9 per cent., and unsatisfactory in nine per cent. The late results, which are the real test of the value of the operation, were excellent in 64.4 per cent.; satisfactory in 26.6 per cent., and unsatisfactory in 8.8 per cent. Combining the excellent and satisfactory groups, which give what may be called the good results, shows that the immediate good results were 90.9 per cent., and the good results nine per cent., which are practically identical. In a series of twenty cases of duodenal ulcer I employed pyloric exclusion by using a strip of fascia from the rectus sheath, according to Wilms's method, in addition to gastrojejunostomy, but thinking that it made little or no difference and only added to the time of operation, I discontinued it. However, on comparing the late results in cases with and without exclusion I unexpectedly found that the cases with exclusion gave the best results. Of the twenty cases I have late reports of nineteen, giving excellent results in 59.9 per cent.; satisfactory in 36.8 per cent., or good results in 94.7 per cent., and only 5.3 per cent. of failures. Of the twenty-six cases without exclusion, twenty-five reported, giving excellent results in sixty-eight per cent.; satisfactory in twenty per cent., or good results in eighty-eight per cent., with twelve per cent. of failures. This may, however, be too small a number of cases to afford a fair

comparison. The exclusion is only intended to be temporary, to afford the ulcer a chance to heal without being irritated by the passage of food; but in one case, fluoroscoped fifteen months later, the pylorus was still occluded.

Suspicion of a simultaneous chronic appendicitis led to the removal of the appendix in sixteen out of forty-eight cases, usually through the median incision, though in three cases a separate muscle splitting incision had to be employed, and in three others the appendix could not be delivered in the epigastric wound. In six more cases the appendix had been removed previously, and in three of these the patient dated the epigastric localization of the symptoms from shortly after the operation. It is undoubtedly true that a number of patients are operated upon for chronic appendicitis who, in addition to or instead of the latter, have a duodenal or gastric ulcer. Appendectomy coincident with gastrojejunostomy does not appear to influence favorably the final result in the cases so treated in this series. The gallbladder was removed in four cases, but only once for stones, the other three times because it was left so raw, after freeing its adhesions to the duodenum or stomach, that fresh massive adhesions seemed inevitable.

A symptom or condition sometimes mentioned by patients on being questioned as to the results, is constipation. In several the bowels, constipated before, were regular after operation; in a smaller number the reverse condition existed. The results in patients who were constipated after the operation, compared with the nonconstipated patients, show this difference, that there are more excellent results, as compared with satisfactory results, when the bowels are regular than when they are constipated. Eructations of gas or sour fluid is another symptom of frequent occurrence. It was noted before operation three times as often as after. It may become quite a matter of habit, and in all but one of the cases noted after operation it was also noted as present before.

In one case the symptoms of ulcer recurred after twenty-one months, and all forms of diet and treatment had no effect. On operation (gastrotomy), two years after the first operation, about three inches of silk or linen thread was found hanging from the inside of the anastomosis. Another three inches was pulled out of the site of the anastomosis. There was no jejunal ulcer. The symptoms were entirely relieved at once. This thread was the outer or serous suture. This was a symptomatic recurrence, but the Mayos have shown that such nonabsorbable sutures are probably the commonest cause of gastrojejunal ulcer. Since that time, four and a half years ago, I have used no nonabsorbable suture, only No. 0 chromic gut, so that nearly all the operations in this present series have been so performed. In a number of these cases we had the benefit, in diagnosis, of a large series of plates taken by Dr. Cole, in clinical cases at the Cornell Medical School. The x ray diagnosis was in each instance confirmed by operation. These patients were also fluoroscoped independently by Dr. A. L. Holland, with practically identical findings. The

great value of fluoroscopy is shown in one of the more recent cases in which an operation had been performed, where Dr. Holland was able to diagnose a duodenal ulcer only after forcibly pressing the stomach aside. The hospital plates did not show the ulcer.

In the group of gastric ulcer cases treated by gastroenterostomy I have included all that I have private records of, going back to 1902, as the group would otherwise be too small. There are eighteen cases in this group, with no postoperative deaths, making a mortality of 2.6 per cent. for all cases of peptic ulcer in which a gastroenterostomy only was done. Among the early cases were three of pyloric stenosis, with dilatation of the stomach, giving remarkably successful results in the relief of symptoms, the patients putting on weight and returning to a normal, active life. The first two operations were done with a Murphy button by the anterior method. The second patient had such a large indurated mass in the antrum that I took it for a carcinoma and told his family that I did not think he could live over a year. Two and a half years later I saw him in perfect health and doing his full work, having gained forty pounds in weight, and I heard of him fourteen years after operation living in California in perfect health.

We ordinarily think that a gastroenterostomy is not adequate to cure a gastric ulcer, except those directly at the pylorus. That some at least of the chronic ulcers can be cured by gastroenterostomy alone is shown by another case, in which the patient was operated upon over nine years ago for an ulcer whose crater could readily be felt on the posterior surface, near the middle of the stomach, adherent to the pancreas. This patient I heard from recently. He is not sick a day, has done hard physical labor since operation, and is nearly seventy years old. In this case a posterior gastroenterostomy could not be done on account of posterior adhesions, so I brought a short loop of the jejunum through the mesocolon and then through the gastrocolic omentum and anastomosed it to the anterior surface of the stomach, making what may be called a retrocolic anterior gastroenterostomy. Since then I have used this method in two other cases of this group and in several resections, mostly for carcinoma. It has always given most satisfactory results; in fact the best results that I have had in gastric carcinoma have been obtained in this way.

Another patient of this group is interesting as having been operated upon at another hospital for perforated ulcer, without gastroenterostomy, seventeen months before. A year later he had a recurrence for which the gastroenterostomy was done, with an excellent final result. There is considerable difference of opinion among surgeons as to whether a gastroenterostomy should be done in perforated ulcer if the patient's condition warrants it. Though this is one of only two cases where I have seen recurrence, I have always preferred to do a gastroenterostomy and feel that the reasons for this course given by Paterson, of London, are quite sufficient.

This man had a stormy and interesting convalescence. Three days after operation, and again seven

days after, he had a large hematemesis with melena. Nine days after operation, the hemoglobin being ten per cent, and the blood pressure so low that it could not be counted, he was reoperated upon after a transfusion of 1100 c.c. On opening the stomach the edges of the stroma were found to be smoothly healed and the source of the hemorrhage was found to be the ulcer. There was no further serious hemorrhage and he made a good recovery.

In this series of gastric ulcer cases treated by gastroenterostomy the late results are known in fourteen, being excellent in eight, satisfactory in three, making 78.5 per cent. of good results. In the three cases marked unsatisfactory one patient when last seen four months after operation, gave an excellent report, but three months later she wrote that she was hopelessly sick, without specifying in what way. Another patient was well for eight months when he began to have stomach symptoms at times, especially vomiting, but no gastric pain. He was operated upon again sixteen months after the first operation and the pyloric end of the stomach resected. Since then he has been free from gastric symptoms, but is still neurotic and has a peculiar pallor, though the blood examination is quite satisfactory. The third patient was entirely well for nearly three years, when gastric symptoms, with hematemesis, returned. His habits of eating, drinking, and smoking were alone enough to provoke symptoms of recurrence of ulcer. On resecting the pyloric end of the stomach the stoma, made at the first operation, was found entirely closed, the only case of the kind that I have met with.

A rather recent case was that of a hydrochloric acid burn where the effects of the acid were confined to the antrum, the distal two inches of which were contracted to a mass with thick walls and narrow lumen, sharply demarked from the rest of the stomach. The symptoms were those of pyloric stenosis and were entirely relieved at once by gastroenterostomy. The effect of the acid is strikingly different from that of a strong alkali, which is exerted mostly on the esophagus and the cardia. Apparently the acid caused a pyloric spasm which retained the acid in the antrum and thus concentrated its action on this portion.

In the few more or less recent cases in this group the ulcer was situated at or close to the pylorus and in five cases a pyloric exclusion was done, proximal to the ulcer, to encourage its healing; but without affecting the final result very favorably. I am inclined to think that the results would have been better if most of these later cases had been resected by the Polya-Reichel method. The best results obtained by gastroenterostomy in the gastric ulcer group have been in chronic pyloric stenosis with dilatation of the stomach. The group of gastric ulcers treated by excision is a small one, only seven cases. The first two cases were treated without gastroenterostomy and were unsatisfactory. A gastroenterostomy was performed later in one of these cases to relieve symptoms and a good result was obtained only after excluding the pylorus at a later operation.

I am firmly convinced that excision alone is a poor operation for gastric ulcer. It seems to interfere with gastric motility and does not relieve hyper-

acidity. Combined with gastroenterostomy, excision, or better perhaps the Balfour cautery operation, may give good results. Excision comes in competition with mesogastric resection, but although the postoperative course of the latter has been very smooth, the final results have not been as good, so that my early enthusiasm for this method has somewhat abated. There are also a few cases of gastric ulcer, well toward the cardiac end, where mesogastric resection is more difficult. At least two in the excision group were of this type and both gave good results. The last one of these is of special interest. A woman aged sixty years had been explored by another surgeon, who found only adhesions. The stomach symptoms continuing she was fluoroscoped by Dr. Holland, who found a very small perforating ulcer posterior to the lesser curvature, about five inches from the pylorus. This was seen only in an oblique view and did not show on the hospital x ray plates. It was found at operation, excised, and a gastroenterostomy done. Owing to its posterior position I could not reach it well with the cautery and it was not suitable for mesogastric resection.

In a group of twenty-six cases of gastric ulcer treated by resection of the stomach four patients died, a mortality of 15.3 per cent. It is interesting to study these four fatalities, all done by the Billroth II method. One patient took the anesthetic badly, pneumonia developed and death occurred on the third day. Another, a man of sixty, had had a gastroenterostomy for ulcer three and a half years before and, though a hard drinker, had been well for three years after operation. He was doing and feeling well on the third and fourth days after operation, but on the fifth day edema of the lungs developed and he died. A postmortem showed serious chronic lesions of the lungs, kidneys and liver. The other two patients had profound anemia from gastric hemorrhage. The first had 830,000 red cells and fifteen per cent. of hemoglobin. He was operated upon immediately after a transfusion of 900 c. c. He did well for several days and then became weaker. Efforts to obtain a second transfusion failed and he died on the seventh day. The second patient had 1,900,000 red cells, thirty-five per cent. of hemoglobin, and lived twenty-five days, finally dying of progressive anemia. This man, fifty-five years of age, had cirrhosis of the liver and a gritty adherent spleen, of approximately normal size. It must be admitted that of these four patients three were very poor risks, two on account of profound anemia and one because of advanced chronic visceral disease. It would have been wiser to do a gastroenterostomy only, in the anemic patients, leaving the resection to a second stage.

Of the remaining twenty-two patients sixteen have reported the late result. Of these six gave an excellent result, seven a satisfactory, and three an unsatisfactory one, making 81.2 per cent. of good results. In one of the unsatisfactory cases, in which a mesogastric resection was done, the patient was reoperated upon six months later, when adhesions narrowing the distal segment were found and freed and a gastroenterostomy done, proximal to the resection. Eight months later the result was excel-

lent, making 87.5 per cent. of good results and 12.5 per cent. of unsatisfactory results. The two remaining unsatisfactory cases were both of mesogastric resection. One was moderately successful for over two years, but the patient was a heavy drinker and was syphilitic. Gastric or duodenal symptoms had recurred after alcoholic excess, when the patient was last seen two and a half years after operation. Hematemesis, occurring repeatedly before operation, had not recurred. The other patient returned five months after operation with gastric symptoms. The x ray suggested a new growth at the pyloric end, although no evidence of this had been found on microscopic examination of the ulcer. He refused operation and was lost track of.

In gastric ulcers situated at or near the pyloric end I do a resection, preferably by the Polya-Reichel technic. If the antrum is normal and the ulcer is three to four inches or more proximal to the pylorus I have done a mesogastric resection. Where the ulcer is so far from the pylorus as to make this operation quite difficult, an excision, or the Balfour cautery method, with a gastroenterostomy, is preferable.

This group includes eight mesogastric resections with no deaths. At first I was strongly in favor of this method, which has the advantage of not requiring a gastroenterostomy, but I have been disappointed with its results. The convalescence is usually smooth and satisfactory. Only five cases have been heard from and, after reoperation in one case and the addition of a gastroenterostomy, the satisfactory results comprise only sixty per cent. It may in justice be said, however, that many of these cases presented the worst types of chronic ulcer in unpromising specimens of humanity. I believe that it has its place in gastric surgery. Five out of the eight ulcers were situated posteriorly and adherent to and sometimes penetrating the pancreas. Excision and cautery are not suitable in these cases and a complete resection involves the removal of a large segment of the stomach. In such cases, adherent posteriorly, I believe that mesogastric resection is indicated.

Four patients were operated upon by the Billroth II method and both of the cases with return records gave good results, one satisfactory and one excellent, the latter done by the retrocolic anterior gastroenterostomy method. It is a striking fact that in four cases of gastric ulcer in which this method was employed, on account of adhesions posteriorly, the end result has been excellent in all in which it is known. But the number of cases is too small to justify definite conclusions. The Polya-Reichel method was used in nine cases, of which eight reported, with five excellent and three satisfactory results, or 100 per cent. of good results. This operation has given much satisfaction. It saves time, as compared with the Billroth II method, and, according to the voluntary testimony of the house staff the postoperative convalescence is smoother and more satisfactory. The Polya-Balfour method was employed with satisfactory results on one patient who had previously been operated upon elsewhere, and in whom the Polya-Reichel technic could not be used on account of adhesions posteriorly. Carcinoma is

known to have developed in one of the eighteen cases of gastric ulcer, not resected, after five and a half years of entire absence of gastric symptoms. The operator could not tell whether it originated in the stomach or pancreas. It caused persistent jaundice. In another case of mesogastric resection the x ray gave a suspicion of malignancy. It is noticeable that the results in private practice are appreciably better as there have been no unsatisfactory results in my private cases. In the majority (71.5 per cent.) of these 109 cases the ulcer has not been removed or cured by the operation. The latter merely puts the stomach in such a condition, mechanically and chemically, that the healing of the ulcer is favored. In addition then these patients should have a dietetic cure and the postoperative period offers ideal conditions for this regimen. A few patients, after obtaining complete relief, have so abused their stomach by alcoholic and dietetic excesses as to bring on recurrence of ulcer or of gastric symptoms.

Again, if bacteria from the gums and teeth sockets are an etiological factor in producing ulcer, we can not expect, much less obtain, continuous satisfactory oral conditions in the majority of hospital patients. In the matter of diet or oral sepsis conditions may continue or recur which caused the formation of the original ulcer and which favor the development of a new one. This applies particularly to hospital patients, and in this class it is important, by education, the follow up system, social service, and similar means, to secure such conditions that the good results may be permanent. In a given case of gastric or duodenal ulcer we cannot guarantee a good result from operation, but we can assure such patients that in a very large proportion of cases, eighty-five to over ninety per cent., suitable operation offers good results, both immediate and lasting. This holds where medical cures have been tried and failed. In fact, in many of these cases, relapses have occurred after one or several such cures, and ulcer patients should be urged to first take such cures if they can give the time for thorough treatment by rest and diet. The relapses after such treatment will leave many patients who should be urged to try operative treatment.

117 EAST THIRTY-SIXTH STREET.

PEPTIC ULCER.

Clinically and Röntgenologically Considered.

BY JOSEPH S. DIAMOND, M. D.,

New York,

Associate Röntgenologist, Beth Israel Hospital.

(Continued from page 63.)

VOMITING IN ULCER.

Vomiting is not a common factor in the ordinary uncomplicated peptic ulcer. It occurs rarely in the duodenal ulcer and is more common in the gastric ulcers. When stenosis takes place, due to cicatricial pyloric ulcers, then vomiting may become a daily occurrence and will depend upon the degree of stenosis. The vomitus in the severe grades of stenosis is large and has the classical appearance of a gas-

trectasia vomitus presenting several layers of food secretion and containing food ingested a day or so before the vomiting.

Such vomitus is pathognomonic of stenosis and when associated with symptoms of ulcer, a diagnosis of callous ulcer of the pylorus can promptly be made. In minor grades of obstruction vomiting takes place at longer intervals. In the gastric ulcers situated about the lesser curvature forming the so-called Haudeck niche, vomiting occasionally takes place at the height of digestion and is due to the irritation set up by the hyperacid contents as well as by coarse food particles being rubbed against the ulcer base. The gastrospasm is so intense that vomiting takes place in the attempt on the part of the stomach to rid itself of the irritating agents. In this type of ulcer vomiting takes place without any obstruction being present, the ulcer usually being several inches away from the pylorus. In one case of chronic perforating ulcer situated high up near the cardia on the posterior wall, the gastrospasm was so intense that vomiting took place immediately after the introduction of food into the stomach before it had a chance to reach the caudal portion. In simple duodenal ulcer vomiting is the exception and will only occur during an attack of marked pylorospasm with retention of hyperacid secretion. Here the pain and burning is so intense that reverse peristalsis sets in and the irritating contents are brought up. When vomiting does not take place spontaneously these patients often induce vomiting by introducing the fingers in back of the pharynx. There are of course cases when a temporary obstruction is brought about by pylorospasm. In vomiting without pyrosis or without any definite relation to meals and other factors other conditions must be looked for to account for its cause.

HEMORRHAGE.

Gastric hemorrhage due to ulcer is computed to take place in about thirty-five per cent. of the cases. It may occur at any time during the course of the disease. It may often be the first symptom in a case of ulcer with an ill defined ulcer history elicited from the patient only after the hemorrhage has occurred. The hemorrhage is usually severe in the deeply eroded ulcers when larger arteries are involved. Often a blood transfusion may be necessary to save life. In duodenal hemorrhage there may be no vomiting of blood. Syncope may be the first symptom, followed by abdominal pains, pallor, rapid pulse and all the characteristic phenomena of acute bleeding. Later, melena develops. There may appear at first a bright red movement when there is a rapid peristalsis and evacuation takes place immediately. This will invariably be followed by tarry stools. If the blood continues to be bright red then the bleeding is from the lower bowel. When hemorrhage takes place in gastric ulcer, vomiting occurs which is bright red and is large in quantity. In the duodenal ulcer when regurgitation of blood occurs in the stomach, the vomitus may be dark red or coffee ground due to retention and admixture with hydrochloric acid.

CHEMISTRY.

In the consideration of the chemistry of the stomach as a diagnostic factor in ulcer, one must

relegate this method considerably behind all others. Taken alone it has no value, for who would dare to commit himself definitely as to the diagnosis of an ulcer upon the chemistry alone? It surely can be done in fifty-five per cent. of the cases by the anamnesis and in as many cases by the study of the röntgen plates. Even a study of the gastric contents in all its phases by the Rehfuß method of fractional titration at fifteen minute intervals continued for two hours will not *per se* settle the diagnosis. The continued late hyperacidity is present in all duodenal irritations whether due to gallbladder disease, or appendicitis, or even epigastric hernia when adhering and pinching the omental tissue. Even carcinoma is not immune from late hyperacidity. With all that, however, it has its place and is of definite value as an adjuvant. Aside from the chemical reaction there is other valuable information to be obtained from an examination of the gastric contents, such as quantity, consistency—or the degree of chymification, color, the presence of mucus, blood, and if on a fasting stomach, the presence of food particles whether macroscopical or microscopical. Again the finding of a hypoacidity or an anacidity such as in achylia gastrica, will at once help us to rule out an ulcer. It may be safely stated that this negative anacid phase is of greater value than the positive hyperacid phase; for while the latter can only be a hint of the possibility of ulcer, the former will exclude it and indicate the presence of another disease. Truly it may be stated that ulcer may sometimes occur in the presence of achylia. These cases are extremely rare and can always be differentiated by the Gluczinsky test, consisting in the administration of a meat meal and removing the contents at the height of digestion when some free acid will invariably be found when ulcer is present.

The interest centered about gastric analysis is still of greater physiological than diagnostic importance. To quote from Rehfuß: "In a résumé of 842 complete curves on various food stuffs with more than twenty thousand titrations we found that forty-five per cent. exceeded one hundred total acidity and after a study embracing three years' work we are prepared to state that no acid figures occurred in disease which could not be duplicated in health. In other words we found that forty-five per cent. of all responses in health showed so-called hyperacidity, while forty-two per cent. of my ulcer series showed the same thing. In other words there is no greater incidence of high acid figures in ulcer or in any other gastric diseases than in health, a fact that raises the extremely important question as to whether an actual demonstrable hyperacidity ever does occur."

Physiologically, however, gastric analysis imparts to us the knowledge of events of gastric digestion as follows: 1, The response of the organ to the direct stimulus of food as well as the psychic; 2, the change from the fasting secretion to a secretion of higher acidity; 3, the control mechanism of the acid content by the duodenal regurgitation. This latter is evidenced by the finding of trypsin and bile at certain phases of the digestive cycle. To compare the merits of the Rehfuß fractional method

of examination with the older Ewald method is not within the province of this paper. Suffice it to state that both possess meritorious advantages. The Rehfuß method informs us of every phase of digestion at fifteen minute intervals from the time of ingestion of the meal up to the end of digestion, comprising about two hours.

Rehfuß has constructed a curve of the normal secretion where the maximum rise of acidity is reached at the end of an hour and then gradually declines to zero at the end of digestion. He further attempted to classify the pathological departures from this normal curve and impart to them diagnostic significance. For instance, a sharp rise within the hour would indicate a gastric ulcer. A rise which continues high and is sustained to the end of the second hour, he designated as duodenal ulcer. Neither of these is pathognomonic and may be found in all cases of increased irritability of the autonomic nervous system, the lesion residing in any one of the abdominal organs. The fractional method also indicates, with a fair degree of accuracy, the time of tryptic regurgitation and if occult blood is found simultaneously with tryptic regurgitation it may point to a duodenal ulcer. The significance of occult blood with the old method of extraction is perhaps valueless as the larger tube may produce sufficient capillary traumatism to give a Benzidin reaction. The advantages from the Ewald method of examination are first, that a better knowledge can be obtained as to the rate of emptying of the stomach, and second, by withdrawing larger quantities, its physical characteristics as well as the amount of mucus can be better studied. By attempting half hourly extractions with an Ewald tube we can approach the Rehfuß method.

Occult blood in the feces.—The presence of occult blood in the feces when the examination is carried out under proper precautions is significant. There are too many factors of safety which minimize the value of the test. The patient must be on a meat free diet for three days. Precaution as to bleeding gums, hemorrhoids, or any other ano-rectal bleeding is to be observed. Such extreme care can only be followed in an institution. Finally the presence of occult blood in carcinoma is a constant factor.

PHYSICAL EXAMINATION.

Physical examination offers only the most meagre information in the diagnosis of peptic ulcer. The so-called tender point upon which the older textbooks lay so much stress cannot be relied upon to corroborate the diagnosis. It is not always present and if too much importance be attached to it one would miss the diagnosis in the majority of cases of peptic ulcer. It manifests itself only when the ulcer is in an active stage, during an exacerbation of symptoms. When the ulcer is large and deep enough; when in the course of ulceration it has reached or closely approximated the visceral peritoneum; when it is in an active inflammatory condition and an exudate is being thrown out; when there is an associated perigastritis or periduodenitis present, only under such conditions is the tender point manifest.

RÖNTGENOLOGICAL EXAMINATION.

Next in importance to the anamnesis in the diagnosis of peptic ulcer is the röntgenological examination; in fact, so closely associated has it become with the routine gastroenterological examination, and so dependable, that scarcely a clinician today will commit himself to a definite diagnosis until it has been substantiated by the röntgenological findings.

History.—Rapid strides have been made in the progress of the röntgenological interpretation of gastrointestinal lesions. The development of the röntgen ray in the diagnosis of gastrointestinal diseases dates back to 1906 when Hemmeter first attempted to demonstrate the site of an ulcer by the adherence of a fleck of bismuth. He was then called a visionary. With the advent of the Rieder meal, however, Riecher succeeded in 1909 in visualizing the cavity of an ulcer and Hemmeter's dream came true. Shortly after, in 1910, Haudeck described in detail the penetrating and perforating gastric ulcer and called it *nischen symptom*, to which his name has since been attached, and it is now known as the *Haudeck niche*. Simultaneously Schlesinger was enabled to set down definite classifications of the various types of stomachs according to their morphology as seen by the aid of the contrast meal, and Holzknrecht, in studying functional manifestations in health and disease was able to formulate the hypothesis of group symptom complex in the various forms of ulcer which has since been called the Holzknrecht symptom complex. A host of observers abroad, Kästle, Rosenthal, Grædel and others added gradually to the morphology, biology and motility of the stomach under normal and abnormal conditions. Simultaneously in this country Pfahler, Carman, Case, Hirsch and others continued independently along similar lines of sign complexes. In 1911, Lewis Gregory Cole, in this country, by the aid of serial röntgen examinations introduced the epoch making studies of deformities of the duodenal cap which has since been established as an absolute sign of duodenal ulcer.

With the visualization of the Haudeck niche, and especially so with Cole's demonstrations of duodenal defects, dates the birth of the direct method of interpretations of peptic ulcer. The advent of this demonstration threw a new light on the method of röntgenological examinations and placed its accuracy on firmer foundations. It tended to revolutionize the older method of indirect examination by the direct method of studying organic structural changes. The trend in this country of late has been to rely chiefly on the latter method, so much so that many röntgenologists and gastroenterologists have totally discarded the symptom complex. The fallacy of disregarding the expression of a disturbed physiological function of an organ under abnormal influences will be pointed out later on. The unbiased observer cannot fail to regard the direct method as of primary importance and the indirect method as of secondary or contributory value. Unfortunately, however, the direct method is not adaptable to all types of cases. Certain localizations of the ulcer cannot be directly visualized. Ulcers in the posterior wall of the vesti-

bule and pars pylorica cannot be seen. A fair proportion of ulcers, if too small or if situated on the posterior wall, are also missed if followed only by the direct method. In the latter type of cases the secondary or indirect method is employed to very good advantage, and the percentage of diagnoses is largely increased.

Before entering into a detailed description of the various methods of examinations, it is important to possess a full knowledge of the normal röntgen ray anatomy of the stomach, as well as its normal physiological functions as observed with the röntgen rays. The following factors have to be considered: 1, Type of the stomach (size, shape, position, axis); 2, tonus (the response or the behavior of the gastric musculature to the introduction of food); 3, outline; 4, mobility and flexibility; 5, peristalsis; 6, gastric secretion; 7, motility.

Type of stomach.—The type of stomach varies with the habitus of the individual, i. e., with the bony framework, the muscular development, and the degree of intraabdominal pressure, which regulates the tone, shape, size, and position of the stomach. There are several types of stomachs. Adopting the Schlesinger classification according to tone they are as follows: a, hypertonic; b, orthotonic; c, hypotonic, and d, atonic. While dissimilar in their röntgen appearance, varying in length, breadth, capacity, position, axis and tone, all are considered normal, each corresponding to the different status of the individual.

a. The hypertonic type, called by Holzknrecht the steerhorn stomach from its configuration, fits the individual of the status apoplectic, i. e., the individual with robust frame, short and wide thorax, and wide epigastric angle. The position of the stomach, like all abdominal organs, in this habitus is high, assuming an extreme oblique to a transverse axis. Relatively small in size it is broadest at the fundus and tapers down at the pylorus which is the most dependent portion. Forsel explains the hypertonic type somewhat as follows: The influence exerted by the strong abdominal muscles and the surrounding abdominal organs causes an increased intraabdominal pressure which accentuates the tone of the musculature of the most active part of the stomach, the so-called sinus (Forsel) or vestibule (Cannon) or antrum pylori. The stimulus thus exerted from without, as well as the high diaphragmatic and liver attachments, causes the lower portion of the stomach to straighten out assuming a transverse position. The pylorus reaches considerably to the right of the median line and the greater curvature is displaced upward about four to six inches above the umbilicus. This type of stomach is generally found in males and is less commonly met with than the other types. When the intraabdominal pressure is increased from other sources, such as pregnancy, obesity, and ascites, the steerhorn type is also encountered.

b. The orthotonic or fishhook type of stomach is the most common form of stomach. It occurs in the medium slender individual. It is the so-called syphon form of Rieder and resembles the letter J. It descends vertically downward from the diaphragm to the level just below the umbilicus.

The pylorus then rises upward for several inches forming a pronounced *incisura angularis*. The pylorus usually overlies the middle or the right border of the spinal column. It has the capacity of maintaining its contents in a tubular form. The diameter of its lumen is equal throughout. The stimulus exerted here from a uniform intraabdominal pressure causes an even contraction of the entire gastric musculature, assuming the vertical or fishhook type.

c. The hypotonic stomach occurs in the individual of the status asthenicus (*habitus enteroptoticus* of Stiller) with weak abdominal muscles, flat abdomen, poor panniculus, long narrow chest with low diaphragm, and correspondingly low position of all the abdominal viscera. The stomach exhibits a relaxation of its longitudinal muscular fibres and is therefore increased in length and is more capacious. It lies entirely to the left of the median line and its most dependent portion sags down into the pelvis. The upper part is narrowed by an approximation of its walls. The deficient intraabdominal pressure robs the stomach and all the abdominal viscera of support, resulting in the stretching of the ligamentous attachments as well as the musculature of the hollow viscera.

d. The atonic type shows the muscular relaxation to an extreme degree and manifests an exaggeration of all the weaknesses of the hypotonic stomach. It forms a borderline between the normal and the pathological stomach. It is met with in the literature under various names; the *hubhöhe* of Haudeck or the water trap stomach of Satterlee and Le Wald. Variations and transition forms between the various types are common. Modifications between the orthotonic and hypertonic or orthotonic and subtonic types are very often met.

Tonus.—Tonus characterizes the muscular tonicity of the organ and is evidenced by the mode of filling when food is introduced. It signifies the behavior of the gastric musculature when a morsel of food enters the cardia or represents the contractility of the muscular walls to direct stimulus of food introduced into the stomach. The stomach in the empty state lies collapsed into a narrow saugeshaped tube, the walls, barely approximating each other. In its uppermost portion under the left diaphragm, overlies the gas bubble or *magen blase* whose size and shape vary according to tone and to the presence of a fasting secretion. In the hypertonic and orthotonic stomach it is usually small. It increases in size in the hypotonic and is largest in the other type. In the collapsed organ it assumes a pearshaped form with the apex below. The *magen blase* in cases of the latter type may be so large as to cause an eventration of the left diaphragm exerting considerable pressure upon the heart. When secretions are present the *magen blase* is supported by the fluid level and appears with a broad, flattened, horizontal base. When food is taken the first portion of it comes down through the cardiac sphincter and stops just below the *magen blase* for several seconds. The duration varies according to the state of muscular contractility or peristole of the stomach. It is largest in the hypertonic and orthotonic types of stomachs. It then slowly slides down tapering below to the

apex of a triangle. Shortly after it is seen to come down along the lesser curvature in a narrow cylindrical form until it reaches the caudal portion. As food continues to enter, it keeps to the lesser curvature and fills excentrically, i. e., from the lesser curvature outward, the greater curvature being pushed downward and outward, the stomach distending chiefly in width. The lesser curvature in virtue of its anatomical muscular arrangement forms a groove called the groove of Retzius or the road of the stomach (*magenstrasse*). In the hypotonic stomach the temporary delay is lessened and is totally absent in the atonic type. The meal is seen to drop rapidly into the caudal portion filling the stomach from below up, only the lower half remaining filled, the walls in the tubular portion collapsed and approximating each other, differing strikingly from the orthotonic form wherein the muscular walls possess the power of sustaining its contents uniformly in a tubular or cylindrical form.

Outline.—The outline of the stomach when filled is smooth and regular, broken only by the *incisura cardiaca* just at the junction of the esophagus with the stomach and low down by the *incisura angularis* at the junction of the *pars media* and *pars pylorica*. One even sees frequently a broad indentation at the greater curvature under the left costal arch due to pressure.

(To be continued)

GASTROINTESTINAL DISTURBANCES IN AFFECTIONS OF THE OCULAR MECHANISM.

By L. WINFIELD KOHN, M. D.,

New York,

Formerly Chief of the Gastrointestinal Department, Temple
University, Philadelphia.

The more thoroughly we become acquainted with gastrointestinal manifestations, the more convinced do we become of the fact that their creation often has its generic stimulus in dysfunction of other apparently remote organs. This stimulus through the medium of the nervous system affects the alimentary apparatus in such a manner as to give rise to the many symptoms commonly ascribed to the stomach and bowels.

For years I have from time to time suspected in many stomach sufferers the existence of visual disturbances by inference, after having noted carefully the facial expression or facial carriage. Upon investigation I elicited that the ocular apparatus was more or less unsuccessful in its efforts properly to adapt itself to an adequate appreciation of the environment. This visual disturbance was found in many instances in individuals who had no suspicion of its presence. Upon questioning them regarding their vision they invariably remarked that their eyesight was faultless or that they never experienced any ocular difficulty. In just such cases does this unconscious ocular disturbance emphasize its importance and frequency as a cause of visceral disorder. The intermediary part that the nervous system plays in this condition is, of course, most important and essential in the creation of the symptoms under consideration.

The ocular conditions ordinarily encountered in the production of these disturbances are anomalies of the eye muscles and refractive errors. Either of these types of eye affections are capable of inducing profound reflex or referred visceral manifestations.

The recognition of the dependence of abnormal body poise and abnormal body expression upon abnormal adjustments of the eyes was forcibly brought out by Stevens (1) a few years ago. The resulting development of peculiar facial expression, of decidedly improper body carriage and of improper physiological chest action was stressed, and the distinct association of diseases of the muscles of the neck and face, diseases of the nervous system, such as chorea, epilepsy and other neuroses with ocular affection had been established. It had even been taken for granted that as a consequence of these disturbances other secondary diseases, such as pulmonary tuberculosis, diseases of the blood and other diseases, followed. We are not absolutely certain in stating how eyestrain lowers an individual's resistance to the extent of rendering him susceptible to dreaded disease, but it seems not improper to suppose that the nervous system is the great medium wherein the damaging stimulus takes its profound hold. It is in this manner, I feel certain, that original disturbances of the stomach and bowels are created from set up excitation in the eyes. Through the medium of the nervous system, either as a conveyor of abnormal stimulation or as a creator of remote disease through its abnormal responsiveness to stimuli, the function of the gastrointestinal tract suffers and as a result for a time our patient suffers from symptoms of neuroses affecting the organs of that tract. These symptoms are commonly found and exist for long periods of time as purely functional expressions until as a result of their overaction definite organic disease establishes itself. This, in my opinion, is the probable manner of creation of visceral disease, not only from the eyes as a source of original irritation, but also from irritation in almost any distant organ.

In this paper, however, we are concerned with the eyes as disturbers of gastrointestinal poise, and it seems that emphasis upon a condition known as ocular declination is indicated. Often patients having no other errors of vision will upon close investigation show declinations of the vertical meridians of the eyes. This condition must always be borne in mind and looked for else its presence will escape detection. This alone may often be the causative factor back of a profound gastrointestinal neurosis. The strain to which the eyes are subjected in this condition is of sufficient moment reflexly to arouse alimentary disruption. Of course, other eye anomalies that are commonly present and more easily recognized, such as refractive and heterophoric errors, will also very often set up digestive disturbances. Before continuing, it might be well to emphasize the fact that any of these ocular disturbances need only be developed to an apparently slight extent and yet may reflexly create severe gastrointestinal symptoms. These eye conditions may consist of either a refractive error alone or a muscle anomaly, and may also at times occur in combination. Following are the

records of two cases, each typifying a distinct ocular anomaly:

CASE I.—Young lady, aged twenty, was referred to me by her brother, who is a physician. This patient had been undergoing observation and treatment at the hands of a number of physicians for months. She was being treated for gastric disease. She gave no evidence of improvement under their care. Her chief complaint was nausea and vomiting. She is of slightly nervous temperament, ate rapidly and drank considerable tea and coffee; had typhoid fever eight years ago. Her present illness began eight months ago with headaches. She had had these terrific headaches off and on for eight months, for which she had been treated by a number of physicians. During the seven weeks prior to my seeing her she had suffered from attacks of vertigo, nausea and vomiting, which occurred as a rule while eating the first morsel of food or immediately after finishing her meal. She never vomited during a total abstinence from food. The vomiting attacks would often continue as long as four hours at a time. These vomiting attacks would most often be followed a few hours later by a profuse diarrhea. These gastrointestinal attacks would occur every few days and would leave the patient in a highly irritable, discouraged mood, as a result of which she would have crying spells. She also gave a history of irregular menstrual function. She had lost fourteen pounds during the past three months, and she presented an emaciated appearance. Physical examination was practically negative, except for a palpable right kidney and slight refractive error. The eyes showed O. D. + .50 — O. S. + .50. Upon inquiry regarding her vision, she contended that her vision was fine and always had been good. Testing her eyes with a Snellen chart convinced me that my suspicion of ocular error was correct. She was fitted with proper glasses and as a result all symptoms disappeared immediately. She has been free from all symptoms for over seven months.

CASE II.—Young lady, aged twenty-seven. Her chief complaint was nervousness and epigastric soreness. Except for frequent attacks of tonsillitis, no further history of important past illness. She was also treated by a number of physicians before I saw her for this condition. The last diagnosis made was that of gallstones. Her present illness began about a year ago with a feeling of general nervousness, a sensation of heaviness in the epigastrium after meals, and attacks of cold hands and feet. She was nervous most of the time. Experienced a shaking sensation in the epigastrium frequently, with no relationship to her meals. She often had a feeling of profound faintness in the epigastrium, at times excessive sweating and cardiac palpitation. The appetite was poor, breath offensive, excessive gaseous eructations, and the abdomen was distended most of the time after a milk diet. Lately had had many diarrhetic movements and attacks of frequent urination. There was a slight loss of weight. The foregoing symptoms plainly indicated disturbance of the vegetative nervous system (vagal portion). Physical examination was practically negative. There certainly was nothing about her physical condition

to suggest a diagnosis of gallstone disease. Her eyes evinced the existence of a slight refractive error and a declination of the eyes. The eyes showed, as in the first case, O. D. + .50 and O. S. + .50 and a declination of the retinal meridians to the right, of only slight degree, however, and affecting only the vertical meridians of the eyes. The simple correction of these ocular difficulties has ameliorated the condition of this patient to such a vast extent as to make me feel that the original cause of the vagal neurosis was in the eyes. Just as in the former case, this patient had no knowledge whatever of the existence of these anomalies in her eyes and thought it very strange that I should lay so much stress upon her organs of vision. The improvement, however, speaks for itself.

It is very evident from the foregoing that subjective gastrointestinal complaints often result from eye disturbances, and it would seem to me that almost any eye disturbance is capable of producing enough irritation to reflexly bring about these complaints, but those most common are anomalies of accommodation, refractive errors and disturbances of the eye movements. It would also seem, here, that a reemphasis of the importance of looking into the question of declination of the meridians of the eyes is indicated. Many eyes are constantly being examined by specialists who seldom look into the condition of the meridians, and as a result a very important factor in the probable creation of reflex disease is overlooked. Many patients, again, owing to the fact that they subjectively experience no trouble with their eyes often lead the physician away from his path of proper diagnosis. Instead of anomalous eyes in these cases setting up eye symptoms, they set up reflex visceral manifestations. To this condition, in which ocular anomalies give rise to no subjective eye symptoms, I have ascribed the title unconscious ocular disease. Eyestrain, conscious or unconscious, is a rather common condition and by all means requires attention, for through its removal or mitigation the general welfare of the patient can be decidedly improved. It seems that eyestrain so conditions the reflex visceral arcs as to result in the establishment of many untoward body symptoms, and these symptoms often show a predominating relationship to the vagus, hence the condition is spoken of as a vagal neurosis. The above cited cases were pure neuroses, yet the physicians in attendance were prone to view the symptoms from an organic viewpoint. After an extensive study of gastrointestinal complaints I feel certain that most of us would agree that the occurrence of gastrointestinal neuroses far outnumbers organic diseases of this tract. For that reason let us eliminate eye difficulties in our search for a cause of gastrointestinal disease. Attention to this matter in my practice has ameliorated the condition, if not entirely cured many of these disorders.

DISEASES OF THE RIGHT UPPER QUADRANT.*

Medical Aspect.

By M. B. KUNSTLER, M. D.,

Gastroenterologist to the New York Diagnostic Clinics.
New York.

We may consider the right, upper quadrant from either the subjective or the objective point of view. The latter is by far the more accurate, for frequently the patient complaining of trouble in this region upon further examination will reveal a far distant lesion; on the other hand, one must also be wary of objective findings since we may get many signs pointing to right, upper quadrant disease, when in reality no such trouble exists. Right sided pleurisy or pneumonia, subphrenic abscesses, herpes zoster, and many other diseases may cause symptoms in the right quadrant resembling, in every way, diseases of the organs in this region and may even bring the patient to the operating table.

The organs included in the region under discussion are the pylorus, duodenum, pancreas, liver, gallbladder, kidney, colon and at times the appendix. To discuss all diseases of each organ would manifestly be impossible, so I propose, simply, to mention the most common disorders and then to discuss, briefly, the subjective and objective symptomatology.

The pylorus.—The most frequent conditions met with at the pylorus are ulcer and carcinoma, the former being by far the commonest. Stenosis of the pylorus, also quite common, gives symptoms in the epigastrium rather than the right quadrant.

The duodenum.—The only common disease here is ulcer although strictures, dilatation and carcinoma arising from the ampulla of Vater have been described.

The pancreas.—Here we get carcinoma, cysts and calculi. All of these are rather rare and give symptoms more in the umbilical and epigastric regions than in the upper, right quadrant. A rather common condition, however, is pancreatitis, either acute or chronic and most often associated with gallbladder disease.

The liver.—Such common conditions as cirrhosis, congestion and syphilis of the liver being more general than local disease need no discussion here, although they often complicate other conditions. Of the local diseases we have tumors and cysts and abscesses. The cysts are almost always due to the echinococcus and the abscesses to the ameba but may also be caused by colon bacillus.

The gallbladder.—Since gallstones were found by Mitchell (1) in three per cent. of sixteen hundred postmortems and by others in five to ten per cent. of cases we must realize how extremely common gallbladder conditions are. Cholecystitis and cholelithiasis are the most frequent, and it appears that females are affected much more than males, and those past forty in the majority of cases. Gee says: "In women past middle age gallstones are so common that one is not wrong to be always suspecting them." The other gallbladder disease of any

*Presented before the New York Diagnostic Society, May 26, 1920.

importance, to be considered, is carcinoma and this is so rare as compared to the previously mentioned diseases as to be almost negligible.

The kidneys and adrenal glands.—It becomes important at times to differentiate kidney diseases from the others. Calculi and infections of the kidneys are perhaps the most frequent conditions, but tumors and hydronephrosis must be kept in mind, as well as perinephric abscesses.

Colon.—Carcinoma is the only disease in this portion of the colon that needs consideration but we must not forget the frequency of reflected symptoms when other portions of the colon are affected.

The appendix.—A high appendix, at times, gives symptoms entirely localized to the right, upper quadrant and must be differentiated from the other acute diseases in this region.

In considering the symptomatology of the right, upper quadrant I propose taking up the principal subjective and objective signs and point out a few differential points.

The cardinal symptom and the one causing the patient to seek medical advice is pain, and the principal finding in diseases of this region is tenderness. We may divide pain into several classes as: 1, the pain of carcinoma, whatever its location; 2, the colics; 3, the pain of ulcer; 4, that of pancreatitis, and 5, of liver diseases. In carcinoma the pain is more stationary and constant, usually worse at night, and of a dull, boring character. There is no relief except by opiates, the one exception being in those rare cases of carcinoma of the stomach with hyperacidity, when alkalis may relieve it somewhat. Gallstones and renal colics cause an agonizing pain that has a tendency to radiate, the former to the right scapular region, and the latter toward the pubis. Relief may be spontaneous with the passage of the stone but usually opiates are required. Appendicular colic is neither so severe nor so steady as the former and has not the tendency to radiate. The pain in ulcer is sharp, gnawing and burning and usually bears a distinct relation to the taking of food which relieves it as do vomiting and alkalis. At times it shows a tendency to radiate toward the left scapular region. Acute pancreatitis gives one of the most severe pains, being cutting in character and prostrating the patient. The pain in liver disease (cyst or abscess) in which I include cholecystitis is more of a dull pressure and is localized to the liver region. It is at times made worse by taking a deep breath and by bending.

In this case, I believe, the subjective signs are worth more than the objective signs for the tenderness in these diseases is quite indefinite, except in cholecystitis and ulcer. In the latter it is usually superficial and localized to the epigastrium, while in the former it is deep and corresponds to the position of the gallbladder or on a line between the umbilicus and the right shoulder. In kidney diseases the tenderness exists in the costovertebral angle and carcinomas cause tenderness wherever they exist. With tenderness we may consider rigidity of the right rectus muscle, which is present in almost all conditions in this region, and is of little

diagnostic value. Masses may also be felt including enlarged gallbladders, kidney tumors, pancreatic cysts or carcinomas and gastric tumors. Of these the gastric tumors are the most mobile and those of the pancreas least so.

Indigestion is next in frequency to pain and includes belching, heartburn, loss of appetite and nausea and vomiting. The principal diseases causing loss of appetite are gallbladder conditions or carcinomas, regardless of their location. The difference is that in carcinoma the patient has an absolute aversion to food, especially meat, while in gallbladder trouble the loss of desire is due to a rather constant nausea. In the latter it is surprising how well nourished the patient remains, even though the anorexia has existed for some time, while in carcinoma a rapid loss of weight occurs. Ulcer patients do not eat simply because they are afraid, but we find that the desire for food is present. They are usually spare and anxious looking, but show no evidence of any marked or rapid loss of weight.

Vomiting may occur in any disease, being of most frequent occurrence in gallbladder or renal colic, appendicitis, ulcer, carcinoma of the stomach and pancreatitis. The vomiting is probably reflex due to pain, but in ulcer or carcinoma it may be due to obstruction. In carcinoma it is of almost daily occurrence and is of a foul, coffeeground character, while in the former it occurs only rarely and gives immediate relief from the pain, a phenomenon that happens in none of the other conditions. Heartburn is often complained of, but the cause is not so frequently corroborated by stomach analysis. Thus, gallbladder patients may complain of it, but I have found that they more often have a tendency to achylia, due, probably, to a gastritis. Ulcer and chronic appendicitis most frequently give a hyperacidity, the latter being much less in degree than the former.

Constipation is another frequent accompaniment of the diseases under consideration and is most marked in ulcer, gallbladder diseases, appendicitis and carcinoma of the colon. In the latter the stool becomes small and may contain blood and mucus.

Jaundice occurs in carcinoma of the pancreas, gallstones, cholecystitis and some of the liver diseases. In the former it is constant, progressive, and of a greenish hue. In gallstones it is more variable and of a yellow color. In cholecystitis, while jaundice is not so marked we commonly get an icteroid tint to the skin, which usually exists in the various liver diseases.

I wish to call attention to certain general points which may bear a part in the diagnosis. The presence of a secondary anemia is of importance in diagnosing carcinoma, providing the other signs are present and a positive Wassermann, or a pernicious anemia, as shown by blood examination may be of extreme value. The consideration of age and sex are of value for gallstones are most frequent in elderly females, while ulcer is found mostly in young males. When carcinoma develops on an ulcer the change of symptoms, rather suddenly, is quite characteristic and should always be considered.

TREATMENT OF TUBERCULOSIS.

Clinical Case Reports.

BY BENJAMIN S. PASCHALL, M. D.,
New York.

Some one has aptly said that it would take a lifetime to prove or disprove the usefulness of any new method of treatment in tuberculosis. However that may be, we think that twelve years is a sufficient length of time to get a fair degree of accuracy in the case of the substance we are about to describe. The results have been so accurate and consistent in both animals and man and the observations have extended over such a comprehensive series in both groups that the conclusions reached will be found to approach very closely the statements made in the following pages. It was shown in the animal experiments that one could predict to a remarkable degree of accuracy just how a given group of guineapigs would appear at autopsy as soon as the standardization values of a given strain of tubercle bacilli had been learned, and that these results could be predicted with the same degree of accuracy as can be obtained in the usual toxin antitoxin measurements obtained in the standardization of diphtheria antitoxins.

We began using mycoleum as far back as 1908, but were soon stopped by our first disastrous laboratory fire, which put a check on our supply for nearly a year. Even at that time it was sufficiently perfected to be entirely satisfactory on experimental animals and so far as we could see in its clinical results, the only drawback being our utter inability to produce an adequate amount even for the few patients who were then taking it.

A consideration of the pathology of tuberculosis is essential in connection with its treatment by any specific means, since the commonest or caseous form of this disease corresponds to a similar condition seen in syphilis in the tertiary stage, the stage of gumma. Primary and secondary stages are seldom seen in tuberculosis but they exist nevertheless and they may be very clearly demonstrated in the experimental animal. Pulmonary forms of tuberculosis are particularly comparable to the tertiary forms of syphilis, so that we might say first, second, third, and fourth stages of tertiary tuberculosis when referring to the usual physical lung findings plus the pathological realizations. In attempting to gain an insight into what our expectations should be in the case of a new and valuable therapeutic agent to be added to our armamentarium let us not lose sight of this pathological vision lest we expect things to happen in a different manner from what will actually prove to be the case.

In the first place antibodies particularly lipases penetrate very slowly into walled off or partly walled off areas of necrosis or into areas of caseation, while tubercle bacilli can lie in these areas without being destroyed for long periods of time. So closely do these caseous areas resemble the gumma that their separate identity was unproved until the discovery of the bacillus by Koch.

In the second place, wax lipases of a specific nature obey the physiological laws commonly recognized as governing the action of fat lipases and are

not called forth and activated except when one of these areas softens down and liberates natural tubercle bacillus waxes into the surrounding tissues or blood stream, or when mycoleum is injected to increase artificially the quantity of these antibodies already present, that is either the real wax or the wax modified as I have already described (2) must be present to activate these antibodies. Therefore destruction of tubercle bacilli can proceed only when there is first an adequate amount of wax splitting antibodies present in the tissues and second when there is physical contact between the bacilli and the enzymes in question.

Upon these facts, by the way, rests the great divergence of results reported by various investigators on the reliability of certain complement deviation tests in the diagnostic field in tuberculosis, for while the nonwaxy portions of the bacillus play such an important rôle in these serological reactions the strictly waxy portions themselves are exceedingly irregular and uncertain in their results for the reasons stated. Of course the wax lipoid proteid carbohydrate complex when used as an antigen is not separated in its entirety by purely physical methods, which further complicates the already complex deviation aspect of the case.

From the foregoing remarks it will be readily appreciated that the rules for treatment must closely follow our present understanding of the most modern methods for treating syphilis. That the time of treatment, the alternation between active courses of treatment and periods of rest between, and the indications for more active courses or longer periods of intermission must bear a striking resemblance to this pathologically similar disease, with the single exception that in the case of tuberculosis treated with mycoleum we are raising the immunity dose by dose steadily and surely to a higher and higher level until finally there comes a time when the patient fails to react any further and is apparently cured.

Sometimes this high level is not maintained and reactions will reappear after a sufficient interval but it is surprising to note the number of patients who once they are brought to this level will hold it to such a degree that a dose administered one, two, and three years later will fail to elicit the slightest response even in some patients who reacted so continuously and so violently that it sometimes seemed as if we never were to arrive at the end of the disease process. These are in general the old chronic fibroid types of the down and out class. Of course, we do not like to treat them and we avoid them as much as possible, but they occur too frequently and are too insistent in their claims upon us to be entirely ignored. For the first year or so there does not seem to be anything happening of an encouraging nature. They are just patiently hanging on of their own accord because we do not encourage them, since we never know in this class which ones have enough lung tissue left and which have not. After the first year, but more often after the second, it becomes unmistakably apparent that the patient is getting well.

And at the end of the third and fourth and fifth years they are still going up, steadily climbing and never slipping backward. One can only wonder how

much punishment the human body can stand and then recover, if given the right chance to do it and time enough to do it in. We cannot ignore these men and women in the future. They will insist that we treat them through the long and weary years. They are the most patient and the hardest to discourage and they are satisfied with so little, but let us try in the future not to have them get this way if we can avoid it, and I think that we can.

There is nothing so common in the world as the practice of selfdeception in nearly all human affairs. That we avoided this from the first was due to the extreme difficulty in producing an adequate amount. It takes from three to six months to prepare a dose and a few seconds to give it, and the number of doses which can be prepared at a given time or in one lot is exceedingly limited. There has never been an adequate amount for us to use in our own practice, and there is not at the present time enough to treat more than a very limited number of patients, so limited that the taking on of a single new patient should have long and serious consideration as to whether or not we can manage it.

Every effort is being made at the present time to make mycoleum available by going into quantity production methods, which will be an engineering task of large and expensive proportions.

The difficulties in producing mycoleum were so great that in the beginning we actually hoped against hope that some substance easier and cheaper to prepare would turn out to be the proper immunizing substance. At first we discounted the very positive reports which a considerable group of patients began to turn in, some of them exceedingly glowing reports on their sudden and unmistakable improvement. We discounted them on the grounds of anything new. Then the laboratory burned out again and we were again without mycoleum for several months. I made a frantic search over the United States for any quantity of dried tubercle bacilli at that time, and I want to take this occasion to thank the biological laboratories and the state experiment stations which helped me out.

Owing to our inability to obtain more than a few ounces of dried tubercle bacilli at the best from the whole country, we tried to put our patients back on tuberculin. They refused and decided to wait for the new laboratory. Some of them waited too long and when we again had it they no longer were capable of reacting. Others reacted once more and again began to make that same unmistakable climb back toward health. It was the first clear cut indication I had that whatever difficulties there might be in the way of producing this substance and whatever its cost of production might be, some way must be found to make it available to sufferers from this disease.

Some of these patients had been with us during the previous fires, and so we had seen patients who were failing on tuberculin in 1908 start gaining on mycoleum in 1909, begin losing again in 1910 when our first fire happened and tuberculin was resumed, gain again in 1911 on retreatment with mycoleum, lose ground again in 1912 on resuming tuberculin once more on account of our second fire

and again start improving in 1913 on mycoleum, when they were finally treated to ultimate recovery.

Prior to 1910 the doses of mycoleum were small as compared to those given at a later date. It was plainly seen that even these doses had a distinct retarding action on the course of the disease in the severe forms and a markedly beneficial effect in the milder forms. It was only after we had very greatly enlarged our incubator facilities that the doses could be increased, and the dose at present given was finally determined to be the minimum amount which would prove sufficient to provoke a lasting immunity in the largest majority of cases. It has, however, been determined that if this standard dose does not provoke a reaction no amount of increase will have the slightest effect. It has already been shown that it is harmless on the experimental animal in practically any amount. I have given the human dose of three c.c. to a tuberculous guineapig without harm.

There are a number of complications and sequelæ which deserve a moment's attention, though they might well be reserved for a future discussion in which methods of treatment are more fully taken up. Accumulations of pus from bone tuberculosis must be evacuated at the earliest possible moment. There is no danger of secondary infections and sinuses discharging over long periods of time. Mycoleum will take care of this feature with promptness and accuracy. On the other hand failure to evacuate pus promptly keeps mycoleum from exerting its specific action and may cost the patient his life.

Patients with intestinal tuberculosis may make a splendid recovery and die from a subsequent obstruction due to adhesions caused by the disease.

Renal tuberculosis is quite as amenable to treatment as are other forms, but a contracted bladder remains a constant discomfort and does not improve much as years go on. It is not advisable to treat renal tuberculosis where the injected bladder does not hold six ounces, unless the patient is highly intelligent and understands thoroughly that there is going to be less and less capacity, even an almost immediate cessation of the process. Long continued toxemia may have left permanent changes in the organs of metabolism and elimination, and these degenerations are not capable of regeneration.

Immunity does not often take place before the age of three, but recovery as late as seventy-five is not uncommon. Alcohol and tobacco depress the blood capability, and excessive smoking may obliterate the power of the formation of immune bodies just as surely as does excessive alcoholism.

Acute miliary tuberculosis does not react except in comparatively early stages of the disease, and if the first three doses do not cause a reaction there is no use of giving any further injections. The same thing may be said of tuberculous meningitis. I have seen a number of these cases and so far have not been able to elicit reactions in any one of them. Some of them have been children and some adults. There may be histological reasons for this though it would seem as if there should be reaction to the disease which undoubtedly exists in other parts of the body

—still the rule of no reaction no recovery holds good in these cases. There are, it is true, some cases of synovitis in which the reaction is satisfactory and the improvement exceedingly slow in proportion, due to the difficulty of penetration of wax lipases, but cases are rare in which the clearing up is not in keeping with the reaction.

As a diagnostic test mycoleum is more accurate than tuberculin and there is never a tolerance produced toward it as there is to tuberculin with evidences of the disease still present. Continued negative reactions at spaced intervals indicate that the disease has been eradicated or else is so thoroughly encapsulated that none of the antibodies can penetrate the encapsulated area.

The effect of the wax splitting enzymes often shows splendidly if samples of sputum are stained and compared at monthly intervals. A description of these changes deserves a separate chapter and will be treated at a later time but in general it may be said that there are several ways in which the phenomena may manifest themselves. There may be a peculiar irregular or moth eaten appearance of the tubercle bacillus as a whole where a portion of wax is eaten away, leaving the rest of the bacillus, or there may be a marked swelling of the whole bacillus with a hyaline appearance which takes the stain badly, or at a further stage of the process there may be a pale, yellowish structure with the characteristic shape and size of the bacillus but with little or no affinity for aniline dyes.

This last is evidently the membranous portion of the cell wall whose composition is at present unknown. These last structures often show a trace of pink color remaining and are the last bodies seen until the patient reports the absence of sputum.

Our experiences with mycoleum extend over twelve years and record many hundreds of cases of human beings and over a thousand experimental animals, beside those experiments done under the auspices of the U. S. Public Health Service.

We have administered several thousand doses during this period in every known form of the disease and have refrained from publishing these results until every important phase of the subject was completely covered and every side of the question thoroughly worked out. The following case reports have been selected to illustrate in general these forms. Nearly all of them were diagnosed by other physicians and referred to me for mycoleum treatment.

CASE I.—In 1908 a young lady (J. C.) was sent to me suffering with lupus of the face. Examination revealed similar areas on the chest, on the nasal mucous membranes, and on the scalp. There was evidence of an early choroiditis and the chest was pretty well scarred up. No particular area, just a diffuse fibrosis, corroborated by the x ray. She was aged twenty-three and gave a history of malnutrition from early childhood, was not underweight but her tissues had a corklike feel. I mention this because it is common in tuberculosis of the toxic or latent variety.

It is the scrofulous child grown up, carrying along with it all the early infection, all the intoxication, all the pathological changes caused by this

constant poisoning going on year after year, and yet because the patient is not emaciated or underweight we have to content ourselves with the unsatisfactory assertion that her tissues are bad, which does not give the picture in the slightest degree. The Wassermann was negative. I gave her a thorough course of tuberculin in the accepted way, with no improvement. Instead, she grew gradually worse until in 1913 I saw her in bed with a typical tuberculous enteritis of the typhoid type, an average daily temperature of 101° to 103° and a pulse of 120 to 130, which condition they told me had been going on for several months. I told the family that the prognosis was absolutely unfavorable, but they begged me to do what I could for her. I accordingly gave her full doses of mycoleum (three c. c.) at three week intervals for the first six doses and once a month thereafter until she had received thirty doses. She made a prompt and uninterrupted recovery and has remained well since. This case is reported to illustrate the effect on a patient long under observation and known to be slowly but surely going down hill with a fatal ending clearly in sight.

What has been said of other tuberculous conditions applies to eye cases also. In all instances the patient had been to a competent specialist and had received appropriate treatment from him or from some one familiar with tuberculin therapy and was finally turned over to me in the hope that mycoleum would prove of some value. We succeeded in obtaining favorable results in all of them and will briefly report a few selected at random from our records.

CASE II.—E. B., aged eighteen, ran a machine in a clothing factory. She was poor and mycoleum was expensive and scarce. She therefore took treatment only when driven to it by the ravages of the disease. She had iritis, episcleritis and corneal ulcers with intense photophobia. Every time she took a few doses, the condition improved to such an extent that she was able to work with comfort and the clinical signs rapidly cleared up. Every time she left off treatment, she remained well for about six months when the condition slowly began to return again, but the promptitude and completeness with which it always cleared up left no doubt in the mind of either patient or physician that mycoleum offered an absolutely reliable therapeutic weapon and left no doubt that the eye condition was progressive untreated. The Wassermann and gonococcic complement deviation tests were negative. The patient had been treated several years with tuberculin without improvement, and her condition had become so bad at the time of her first dose that there was every indication that she would have to have the eye removed, and she had been told that this would have to be done in a short time. She made a complete recovery with a perfectly useful eye. The time of treatment was from 1914 to 1916 and the number of doses sixteen in all.

CASE III.—Dr. G., aged forty-five, tuberculous iritis with intense photophobia confining him to a darkened room during the intermittent attacks. Three doses of mycoleum in 1914 and one in 1916.

No return of symptoms since that time and thinks the improvement entirely due to its action. There was no doubt about the diagnosis, as there were sclerocorneal ulcers containing tubercle bacilli.

Pharyngeal ulcers are of peculiar interest in that they are so spectacular. This case was Wassermann negative and had been diagnosed and treated with tuberculin very thoroughly without any great improvement.

CASE IV.—Mrs. A. O. T., aged thirty-five, married; husband tuberculous. First seen in 1911; condition was diagnosed as diphtheria by the attending physician and three doses of antitoxin were given without effect, except to produce such an erythema as to be rediagnosed by another physician as scarlet fever. Indeed the suddenness of the onset, the high fever and pulse and apparently well nourished condition made a tuberculous ulcer a remote consideration, but it persisted and continued to spread as weeks went on, and I saw her at a later date. Scrapings of the ulcer edges revealed the presence of tubercle bacilli, and later tubercle bacilli were obtained in the sputum coming presumably from the lungs, which showed distinct lesions. I wanted to give her mycoleum at once, but she looked upon it as an experiment, and as she had been sent to me for tuberculin treatment, I gave her tuberculin for a year with no results, as at the end of the year the ulcer was greatly increased in size and had involved the fauces and was so painful that she was unable to take any solid food. At this time she became discouraged and refused further treatment of any kind. I did not see her again for about five months, when things had become so bad that she could not even take liquids and her pulmonary lesions were rapidly increasing. She had lost weight, thirty or forty pounds, and her outlook was absolutely unfavorable. I gave her mycoleum and forced it at close intervals, giving her in all twelve doses. She made a complete recovery; the throat healed and at the end of six months she returned to her normal weight. I heard from her from time to time for several years, and when last heard from she was still in good health with no return of her tuberculosis. She finished mycoleum treatment in 1912 and reported as late as 1917.

CASE V.—C. D., aged thirteen, had suffered from cervical adenitis for five years, and already had several chains of glands removed by operation. They seemed to appear in crops first on one side and then on the other, but she was never free from them. She was given ten doses of mycoleum in 1914, and there were a number of small calcified nodules left which were removed the following year by a surgeon. I was told afterward that the appearance was retrogressive as far as the disease was concerned. The surgeon left drainage and was surprised to see the sinus heal immediately.

CASE VI.—M. F. had cervical adenitis, was treated with tuberculin without any particular benefit, and the Wassermann was negative. She was twelve when put on treatment and received twenty doses in 1913-1914. She had a very severe eczema over the whole body, which had been there since she was a baby, and which constantly increased in intensity.

This entirely cleared up by the time she was ready for discharge, and the cervical glands disappeared though they were never large. Her general health changed in a very noticeable manner. She was the typical sickly scrofulous child and belonged to a sickly scrofulous family. She suddenly shot up to womanhood and at fourteen was a patient to be proud of. She has remained well since.

Genitourinary tuberculosis without undue bladder contraction is a satisfactory form to treat. I have seen old chronic pulmonary cases drag their weary way along for months before any definite improvement could be seen. I have had desperate cases of general miliary tuberculosis give a definite clear reaction to mycoleum, indicating that they were still capable of being immunized, and then keep one guessing as to whether or not the positive reaction was a safe prediction of ultimate recovery. Yet a patient with genitourinary tuberculosis whose bladder must be emptied every hour or oftener, day and night, and who is utterly worn out from lack of sleep, suffering from pain and a constant desire to urinate, makes as already indicated an ideal one for the uninitiated to observe for the first time. Following the first dose in a local involvement of this kind, there is usually no setback. The patient simply makes a steady and uninterrupted recovery if he follows directions. The following report illustrates a failure to carry out our instructions on the part of the patient.

(To be concluded)

LONDON LETTER.

(From our own correspondent.)

Annual Lady Priestly Memorial Lecture.

LONDON, May 4, 1920.

Sir George Newman, chief medical officer of the Ministry of Health, delivered on April 22d, for the National Health Society, at Robert Barnes Hall, in the building of the Royal Society of Medicine, the annual Lady Priestly Memorial Lecture, which was instituted for the purpose of organizing annually a public lecture on whatever subject connected with public health might be considered most important at the time. No better man could have been found to deliver a lecture dealing with public health than Sir George Newman and his choice of subject, *The Place of Public Opinion in Preventive Medicine*, was peculiarly apt. He pointed out that some kind of public opinion, had no doubt existed from the earliest history of mankind. Sir Robert Peel defined that opinion as consisting of "a great compound of folly, weakness, prejudice, right feeling, obstinacy and newspaper paragraphs." That definition contained at least some ideas which were, perhaps, characteristic of public opinion today. Whether or not, the world was moved today, as never before, by the indefinable power of public opinion, governments, as well as national habit and custom, were impelled or moulded by the man in the street. He was master, the government was his servant. Referring to preventive medicine the

lecturer said that during the last half century, the increase of physiological and pathological knowledge, including that of infection, had been one of the outstanding features of the age. He now knew two certain facts about disease; first, that it is not something arbitrary, capricious, occult or accidental but is an effect of definite causes and conditions; secondly, that these causes and conditions are in a large and increasing measure controllable by man. Today, for the first time, public and personal health had become purchasable. There were two things we desired, health and long life, in other words, to reduce and if possible to abolish invalidism and physical disability and to postpone the event of death. It was to make human life better, larger, more capable and useful, happier, and to prolong our days.

The coming of the Ministry of Health meant a new sort of attack on the strongholds of disease. It meant, of course, increased intervention by the State, improved organization, central and local, a bolder policy. But there was a further factor in reform which was in some ways more important than all these, namely, an educated community and an enlightened public opinion. "As the science of government becomes more representative of the aspirations of the people as a whole, so also its practice becomes more dependent upon their education and equipment. Only an educated people is an effective and healthy people." The education required was not technical instruction in hygiene alone, but an informed humanism which welcomes and understands the growth of medicine and accepts its results boldly and gladly on behalf of all mankind. In the opinion of the lecturer England would not get much further in perfecting her national health organization until the average citizen has been educated to think, and to act as knowledge demands. This statement applies with equal force to America and all countries.

The elements of health for the body were nutrition, fresh air and exercise, and he pointed out that the food of the working classes in Great Britain was, generally speaking, unsuitable, unnutritious and badly cooked and served. The reason was not poverty, but lack of knowledge of the right food to buy and how to cook it. Emphasis was laid on the need for well ventilated factories, workshops and dwelling rooms. The great value of games and recreation was also dwelt upon. And with regard to games and recreation for women, the source of the new race, he said that if music and dancing, golf, hockey and tennis were good for any young woman they were good for all. Sir George proceeded to show how knowledge necessary for the maintenance of health and promotion of sound physique was equally necessary for the prevention of disease. Invalidism, disease and premature death were due to a relatively small number of morbid conditions. A large proportion of these diseases were directly preventable.

The chief hindrance in the practice of prevention was lack of knowledge on the part of the public. It was now known, for example, that four principal diseases, namely, pulmonary tuberculosis, influenza, poliomyelitis and cerebrospinal fever,

were conveyed from person to person by the inhalation of the causal microbe. Protection could be secured only by safeguarding one person from another on the individual scale. A clean mouth, clear breathing passages, abstinence from spitting, sneezing, coughing or shouting would go a long way toward the prevention of these diseases. The lecturer went on to show how considerably other groups of maladies, such as dyspepsia, septic wounds and diseases contracted by infection, infant mortality, etc., could be lessened by the dissemination of some simple knowledge as to their causation.

A further purpose of an enlightened public opinion in regard to preventive medicine was that the assent of the community might be won for sanitary reform and its consent secured for sanitary government, imperial and local. Hygiene could only become an expression of the national life if the people consented and were willing to advocate and carry out its reform. Mere legislation in this as in other fields would prove abortive if not supported by an intelligent public opinion. The lecturer recapitulated the principal items of a national policy in preventive medicine as follows: 1. Importance of rearing a healthy race. 2. Maternity and the care and encouragement of the function of motherhood. 3. Infant welfare. 4. The health and physique of the school child and adolescent. 5. Sanitation and an improved personal and domestic environment, including food, water supply and housing. 6. Industrial hygiene. 7. The prevention and treatment of infectious disease. 8. The prevention and treatment of noninfectious disease. 9. The education of the people in hygiene. 10. Research and the extension of knowledge.

In discussing the means of educating public opinion Sir George Newman dealt first with the young. What was needed was to give the child and adolescent population of all social classes and grades, first, a body of facts concerning personal health, and secondly, an experience in the practice of hygiene, the habit of healthy living. The two elements must be taught together and the subject pressed home every week in every school in the land. Arrangements must be made in all schools for physical training and instruction. To appeal to the youth and adolescent of the country, however, was not sufficient. We needed much wider methods of propaganda. We must avail ourselves of the services of all who know in behalf of all who do not know. All doctors, nurses, midwives, health visitors, sanitary inspectors and welfare workers should be missionaries of hygiene. The admirable work of the voluntary health societies could hardly be overestimated. Particularly valuable was such a campaign as that represented in national health work. Why not have a Health Day as well as an Empire Day or Hospital Day, as a regular feature of our national life? Again it was impossible to exaggerate the significance of the newspaper press as an educational health agency. The press had done much, but it might do more. It was after all the daily literature of the people. Lastly, the government itself could not be absolved from its share of responsibility in begetting a wise public opinion in health matters.

tation through the mail as second class matter.

NEW YORK, SATURDAY, JULY 17, 1920.

CLINICAL FORMS AND TREATMENT OF BILIOUS HEMOGLOBINURIC FEVER.

There are two forms of bilious hemoglobinuric fever, each having a distinct symptomatology. The first, which breaks out at the time of a violent attack of malaria, commences with a severe chill. The temperature attains 103° to 105° F, accompanied by restlessness, occasionally by delirium, and attempts at vomiting. The urine is scanty and light red in color. There is a mild yellow tinge to the skin, the pulse is rapid but regular, the spleen hypertrophied, and the liver slightly enlarged.

In the second form of the process, which arises in chronic malarial patients when some secondary cause intervenes, there is no chill, the temperature never goes as high as in the first form of the process, while the restlessness and vomiting are absent. The urine, which is voided in large amount, is melanic, the tint of the skin is frankly icteric, and the pulse depressible. The heart sounds are diminished in clearness and the spleen and liver are hypertrophied. This is the more dangerous of the two forms because the patients have been weakened by long continued malaria, the cardiac muscle is wanting in tonicity, while the hemoglobinuria reaches its maximum degree from the onset.

The general treatment consists of an enema given at a temperature of 99° F. followed by a dose of sodium sulphate. This should be repeated every morning. In the first form twenty centigrams of sulphate or hydrochlorate of quinine should be injected at once and after this has been done the urine

should be collected at least every two hours and the tube containing the sample held against a sheet of white paper in order to appreciate the color. The red tint of the urine slowly decreases in intensity. The temperature is simultaneously taken with each urine examination and is compared with the successive notations of the colorimetric scale of the urine. The quinine injection should be repeated only when there is a drop in the temperature and a decrease in the intensity of the color of the urine. When the proper time has come, which may be delayed for eight, ten or even twelve hours, it is better to give two injections of ten centigrams each at one or two hour intervals than a single injection of twenty centigrams. When the temperature has become normal and the urine clear, the patient's condition should be followed and the heart especially watched.

In the second form of the process a very large dose of camphorated oil should be injected at the onset and the urine and temperature examined and compared, as stated above. The hemoglobinuria is, in this case, regarded as a secondary process by Houssian, and he believes that the cardiac disturbances are the all important feature of the condition. If they subside, the hemoglobinuria will have a tendency to disappear spontaneously. Diuretics are useless in this form and quinine will only activate the destruction of the red blood corpuscles. It is only later on, when the hemoglobinuria has become less intense, that quinine and arsenic may be exhibited to control the paludism.

THE ONTARIO MEDICAL ASSOCIATION.

On May 25, 1920, and the three following days, the annual meeting of the Ontario Medical Association convened in Toronto under the presidency of Dr. Fred W. Marlow. It is said to have been one of the most successful meetings in the history of the organization. Perhaps the direct contributory cause of this may be assigned to the rather extensive and ambitious efforts of recent years in the formation of county societies and district societies which, along with the city societies, have now representation on a body styled the Committee of General Purposes. This arrangement gives widespread and rather close connection with medical men in all parts of the province of Ontario—and where is the man who does not like to have a seat in the inner circle?

Immigration and alcohol were live topics. Regarding the former, the special committee on

legislation recommended that classes be established by school boards for the training of mentally defective children; that stringent immigration laws against bringing mental defectives into Canada be enacted; that there be legislation to prevent their marriage; and that students in medicine be more intensively educated in psychopathology. There are seven government vendors of liquor in Ontario—two in Toronto, and one each in Ottawa, Hamilton, Windsor, London and Kingston. It was the opinion that the number of these should be increased and that their offices should remain open on Saturday afternoons and Sundays. It was also suggested that doctors should refuse to write prescriptions for government vendors, as all such prescriptions should go to druggists. That the Ontario Temperance Act is a very unpopular measure was evidenced; and it is even so considered by the Government of the province itself, which has appointed a special committee of the legislature to inquire into the administration of the act. There is a growing feeling that not a quart but an eight ounce bottle should be the maximum for prescriptions.

President Marlow felt strongly that there should be some system for checking up the general practitioner. Particularly was he caustic in his remarks on the man who was too busy to take a few days off to attend the meeting of the provincial medical organization. This, however, was an old topic even before the president came into active propaganda work on this topic. Dr. Marlow's special designation of the shirkers was chronic fossils. It takes a long time to become a fossil, but what would an acute fossil be like? Dr. Marlow would give the Medical Council of Ontario power to expel, suspend, or order further courses of study where a practitioner was found incompetent. Consider what is ahead of one as an old man! The great lack of hospital accommodation and of professional nurses was another subject dealt with by Marlow. He thought that the extension of hospitals must be faced by the municipality in the future, and that there was a particular need for women trained as nurses and with a good knowledge of domestic science. His pronouncement on medical education against the six year course was wise, in that the student was stuffed and would be better for having opportunity for postgraduate study.

Dr. Charles W. Service, of West China, pressed upon the association the needs of the West China Medical School. In China lack of sanitation was the greatest problem. Mortality was probably forty to fifty to the thousand in adults and fifty to seventy to the thousand in children. The medical and surgical fields were enormous. He said that it

was intended to make the West China Medical School a Canadian institution.

A very interesting address was that of Dr. Ariel W. George, of Tufts Medical College, Boston. It was on the use of the x ray in the interpretation of symptoms referable to the biliary system, and was illustrated with lantern slides. Prof. N. W. Percy, of the University of Illinois, dealt with the subject of the transfusion of whole blood, which should be carried out only after careful selection of the donor. Its use in pernicious anemia occupied a good part of his address. Evidence was forthcoming that the high cost of living was affecting the medical practitioner in Ontario. Indeed, in some cities and towns fees have already been advanced from two dollars to three dollars a call and five dollars for emergency visits and visits after six o'clock p. m. Additional advance in fees for insurance examinations was a live topic, and larger fees for workman's compensation injuries were demanded. Dr. Gwyn, Toronto, in reading a paper on influenza, said that this disease generally came in three successive waves, that last fall witnessed the final wave and that Ontario was not likely to be visited again in the fall of 1920.

THE TREATMENT OF DYSPHAGIA IN TUBERCULOUS LARYNGITIDES.

Dysphagia is one of the most common symptoms of tuberculosis of the larynx, at least at the terminal phase of the process, and is one of the difficulties encountered in the care of those unfortunate patients who are unable to eat, and contributes toward making tuberculosis of the larynx one of the most distressing affections with which we have to deal. Its cause resides in the edema, or rather the infiltration of the upper structures of the larynx—epiglottis, arytenoids, and arytenoepiglottic folds, with or without ulceration.

The sensory nerve, whose territory corresponds with the laryngeal vestibulum, is exclusively the superior laryngeal which, before penetrating into the cavity of the larynx, passes very superficially between the lower border of the os hyoid and the upper border of the thyroid cartilage. If the examiner pushes the left side of the larynx with a finger of the right hand, the thumb of the same hand will distinctly feel the large horn of the hyoid, the horn of the thyroid and the free thyrohyoid space. A little stronger pressure over this area, especially on the diseased larynx, will at once give rise to rather sharp pain, shooting to the external auditory canal, on account of the superior laryngeal nerve being directly under the examiner's finger.

The dysphagia can be controlled in most cases by

regional anesthesia and the best procedure consists in pricking the nerve at the point where it underlies the skin, and injecting a few drops of eighty-five per cent. alcohol along the nerve. There is a sharp pain at first, extending to the ear, which proves that the injection has reached the proper structures. The pain lasts for but a few seconds and is followed by a complete analgesia and the entire disappearance of the dysphagia. The effect on both the mental state and the physical condition of the patient is naturally considerable. It is curious to note that the edema and infiltration diminish and the mucosa assumes its normal volume. On the other hand, the laryngeal lesions can be directly treated and the patient properly fed.

This anesthesia may last for several months following a single injection, in other subjects the amelioration is for only a few days, but it often happens that after six or seven injections a permanent anesthesia ensues. This treatment is practically devoid of danger, if the operator exercises a little care, and does not require any special technical knowledge other than the requisite amount of knowledge of regional anatomy which every practitioner should possess.

ILLINOIS AND HER SUBNORMAL CITIZENS.

"I am convinced that thousands of persons daily walk the streets of Chicago who, because of their mentality, are not fit to be at large. Should they be arrested for petty larceny they may be imprisoned two or three years, but imprisonment or psychological care will not create brains and a man cannot be always in prison in case he should commit some crime when released." J. L. Whitman, superintendent of prisons for Illinois, in saying this welcomes the new parole law of from two to five years for the subnormal prisoner.

Even with all that societies can do for these and for defective children they remain a care to the State, even a menace to society. At the end of 1919, Illinois alone had 19,194 cases classed under mental in her penal institutions.

Of course if they could always be kept imprisoned for fear of what they *might* do, matters would be more simple, but it is only when a paroled person feverishly and gustatorily commits some horrible crime that shocked normals concur in the advantages to be gained from institutional life run on a scientific and humane basis. But it will be costly, for beside those actually committed as subnormal, preventive work beginning, one might almost say, at a prenatal stage, must have more and more recognition. Illinois is now building a large graded prison offering opportunities by a progressive merit system, and the Department of Public Welfare is well staffed with clever men, but will leading citizens on its opening day give due reflection to the horrible necessity such a building suggests in any State?

FAMILY TREES.

There are many men in the United States who, when in America, will loudly proclaim their contempt for aristocrats, blue blood, and lordly castles, but such men are often found in the British Museum or the Royal College of Arms seeking to trace their family back to some denounced aristocrat or old county family in England.

When compiled such a document is of great interest to all relations, but names, dates, and titles do not enthuse the physician or the student of eugenics, who would gain more interesting facts from the family tree of Mark Twain, which had, as the owner remarked, only one branch (with a noose attached).

The Eugenics Record Office rather fancies such one branched trees; at any rate, it is offering four leaved ones to those who will follow instructions given and chart in four generations giving as much as possible concerning their character. The *Family Tree Folder*, when filled in, will be a complete modern eugenic record. It will give natural, physical, mental, and temperamental traits, so that their segregation and recombination may be traced in a definite manner.

News Items.

Yellow Fever in Vera Cruz.—A press dispatch from Vera Cruz states that several new cases of yellow fever have occurred there.

Irish Medical Meeting.—The annual meeting of the Irish Medical Association was held June 17th under the presidency of Dr. J. Marshall Day. Dr. E. Magennis was elected president.

United States Hospital No. 28 to Close.—Announcement has been made that U. S. General Hospital No. 28, at Fort Sheridan, Ill., will probably be closed on October 1st.

Dr. E. P. Lyon Honored.—Dr. E. P. Lyon, dean of the medical school of the University of Minnesota and formerly dean of the St. Louis University, has been awarded the honorary degree of LL. D. by the latter institution.

Dr. S. Josephine Baker Appointed.—Dr. S. Josephine Baker, director of the Bureau of Child Hygiene of the Department of Health of New York City, has been appointed consultant in child hygiene for the United States Public Health Service and has also received a commission as surgeon in reserve of the Public Health Service.

Plague Increasing in Southern Regions.—Reports of cases of bubonic plague continue to come in from Texas and Florida. Last advices were to the effect that eight cases have occurred in Austin, Tex., with three deaths; at Galveston there have been three cases of plague, with two deaths, and there have been four cases in Pensacola, Fla.

Health Bureaus Coordinated.—A coordination of the work of the U. S. Public Health Service and that of the Bureau of War Risk Insurance in caring for sick and disabled veterans of the war is shortly to be achieved by placing the two bureaus under the direction of one assistant secretary of the treasury.

Appointment of Dr. Benjamin White.—Dr. Benjamin White has been appointed director of the division of biological laboratories of the Massachusetts State Department of Public Health, to succeed Dr. Milton J. Rosenau, resigned.

Honor to Dr. Alonzo E. Taylor.—Dr. Alonzo E. Taylor, professor of physiological chemistry at the University of Pennsylvania, has been awarded the honorary degree of Doctor of Laws by the University of Wisconsin.

Brazilian Hospital Given to France.—The Brazilian hospital installed during the war at Vaugirard, France, at a cost of ten million francs, has been offered by the Brazilian government to the French faculty of medicine. Although the hospital will serve for the study of general medicine and surgery, it will be used more particularly for teaching practical surgery to Brazilian medical students in Paris.

United States Civil Service.—The United States Civil Service Commission announces examinations on October 1st for the following positions: Medical intern, St. Elizabeth's Hospital, \$1,200 a year and maintenance; bacteriologist, U. S. Public Health Service, \$130 to \$180 a month; assistant bacteriologist, \$70 to \$90 a month; junior bacteriologist, \$70 a month; junior bacteriologist, part time \$30 to \$50 a month.

New York State Civil Service.—The Civil Service Commission of the State of New York announces examinations on July 31st for the following positions of interest to medical men: Assistant medical examiner, State Industrial Commission (write for special circular); physician and assistant physician, state institutions, \$1,500 to \$1,800 and maintenance; physician (psychiatrist), Syracuse State School for Mental Defectives, \$2,000 and maintenance.

Appointments and Promotions at the Rockefeller Institute.—The board of scientific directors of the Rockefeller Institute for Medical Research announces the election of Dr. Winthrop J. V. Osterhout as a member of the board to succeed Dr. Theodore C. Janeway, deceased.

The following promotions and appointments are announced: Dr. Alfred E. Cohn, hitherto an associate member in medicine, has been made a member. Dr. Peyton Rous, hitherto an associate member in pathology and bacteriology, has been made a member. Dr. Donald D. Van Slyke, hitherto an associate member in chemistry, has been made a member. Dr. Francis G. Blake, hitherto an associate in medicine, has been made an associate member. Dr. John H. Northrup, hitherto, an associate in experimental biology, has been made an associate member. Dr. James H. Austin, hitherto an assistant in medicine, has been made an associate. Dr. Harry W. Graybill, hitherto an assistant in the department of animal pathology, has been made an associate. Dr. William C. Stadie, hitherto an assistant in medicine, has been made an associate.

The following have been made assistants: Miss Helen L. Fales (chemistry), Dr. Philip D. McMaster (pathology and bacteriology), and Miss Marion L. Orcutt (animal pathology).

The following new appointments are announced:

Dr. Harry Clark, associate member in pathology and bacteriology; Dr. Pierre L. du Nouy, associate member in experimental surgery; Dr. Paul H. de Kruif, associate in pathology and bacteriology; Dr. Lloyd D. Felton, associate in pathology and bacteriology; Dr. Rudolph W. Glaser, associate in the department of animal pathology; Dr. Carl A. L. Binger, assistant in medicine; Dr. Ralph H. Boots, assistant in medicine; Dr. Louis A. Mikeska, assistant in chemistry; Dr. Charles P. Miller, Jr., assistant in medicine; Dr. Eugene V. Powell, assistant in x ray; Dr. Leslie T. Webster, assistant in pathology and bacteriology; Dr. Goronwy O. Broun, fellow in pathology and bacteriology; Miss Katharine M. Dougherty, fellow in pathology and bacteriology; Dr. André L. E. Gratia, fellow in pathology and bacteriology; Mr. Thomas J. Le Blanc, fellow in pathology and bacteriology; Dr. Giovanni Martinaglia, fellow in the department of animal pathology; Mr. Henry S. Simms, fellow in chemistry.

Dr. Marshall A. Barber, hitherto an associate in pathology and bacteriology, has accepted a position with the U. S. Public Health Service to do field work in the Malaria Research Laboratory, Memphis, Tenn. Miss Angelia M. Courtney, hitherto an associate in chemistry, has accepted an appointment to do chemical research work in the Medical School of the University of Toronto. Dr. Carl Ten Broeck, hitherto an associate in the department of animal pathology, has accepted an appointment as associate professor of bacteriology, with the Peking Union Medical College. Mr. Earl P. Clark, hitherto an assistant in chemistry, has accepted a position with the Bureau of Standards, Washington, D. C. Dr. Ferdinand H. Haessler, hitherto an assistant in pathology and bacteriology, has accepted an appointment as resident pathologist in the department for nervous and mental diseases in the Pennsylvania Hospital at Philadelphia. Dr. Arthur B. Lyon, hitherto an assistant in medicine, has resigned to enter private practice.

—◆—
DIED.

BROWN.—In Boston, Mass., Dr. Frank Byron Brown, aged fifty-seven years.

CARPENTER.—In Pottsville, Pa., on Sunday, July 4th, Dr. James Stratton Carpenter, aged sixty-one years.

CONKLIN.—In New York, N. Y., on Monday, July 5th, Dr. Fanny Donovan Conklin, aged seventy-four years.

COPE.—In Nazareth, Pa., on Sunday, June 27th, Dr. Thomas Cope, aged seventy-three years.

CURTIS.—In New Britain, Conn., on Saturday, June 26th, Dr. John Henry Curtis, aged fifty-six years.

GRAY.—In New York, N. Y., on Saturday, July 3rd, Col. William W. Gray, aged sixty-nine years.

HOLDRIDGE.—In New York, N. Y., on Saturday, July 3rd, Dr. Walter Henry Holdridge, aged forty years.

KELLOGG.—In Sacramento, Cal., on Tuesday, June 22nd, Dr. Donald A. Kellogg, aged fifty-five years.

LANE.—In Philadelphia, Pa., on Wednesday, July 7th, Dr. Peter Henry Lane, aged forty-one years.

PAUSON.—In San Francisco, Cal., on Tuesday, June 29th, Dr. Charles Arthur Pauson, aged thirty-eight years.

SCOFIELD.—In Dalton, Mass., on Tuesday, July 6th, Dr. Walter W. Scofield, aged sixty-six years.

THOMPSON.—In Snohomish, Wash., on Sunday, June 20th, Dr. Thomas F. Thompson, aged seventy-one years.

Book Reviews

THE SIN OF WEAKNESS.

Peter Middleton. By HENRY K. MARKS. Boston: Richard G. Badger (The Gorham Press), 1919. Pp. v-370.

There have been novelists of the past who intuitively and unconsciously used the tools of psychoanalysis to represent their characters more truly than the superficial observer would appraise them. The writers of the present with a conscious appreciation of psychoanalytical investigation have usually handled the subject rather clumsily. Here, however, is a writer who has revealed the unconscious side of his hero's character with the clearness, the interpretation, the convincingness of a technical psychoanalyst, and yet no awkward, inartistic tool work is visible.

One wonders whether, as such truer representation of human lives becomes more common, literature will have to substitute some other name than hero for the chief character of a story. Literature has gradually descended from gods to demigods, from demigods to heroes, and now to what? Will it not be a truer, more helpful revelation of a weak and struggling fellow man, and the reason for success and failure? As the field of knowledge regarding ourselves and others is thus enlarged we shall lose nothing of a genuine appreciation of human nature and be better able to develop a genuine heroism which meets successfully the actualities of loving and living.

Peter Middleton was sufficient for neither of these. He did not know what it was to discover and realize himself, he did not know what was expected of a genuine masculine self. He cherished a lovely idealism, a temperamental, dreamy appreciation of beauty. He called it artistic but it had none of the true artist's strong creative tendency. It was rather an escape from healthy activity upon external things and deeper still from a recognition of inner unyielding fountains of power. The repellant austerity of his mother must have early driven those deeply within and fixed them for Peter where they were incapable of being tapped. At least only a woman in later life who comes first as a wiser mother, deeper in tender creative wish and yet with an ability to become the equal adult companion, succeeds in awakening any healthy outward reaction on the part of Peter. That, however, was too late for him to escape the bonds which his weaknesses had woven about him so that the abject failure of his life could not be stayed.

Until it was too late Peter had never learned what it was psychologically and physically to be a man. His idealism was not only a substituted escape from the sterner facts of reality, it actually also turned him back to feed upon himself. There is no escape from the results of a morbid absorption in self except through an outgoing relation to the external world. Peter could sustain such a relationship only for a brief time and in an incomplete ineffectual way. The products of introversion are self pity, of which Peter bore a heavy load, shameful inadequacy in confronting insincerely aggressive types of men, spinelessness and indecision in the face of the clinging affection and desires of another, which form his

final entanglements and lead to his complete undoing.

The author discloses with an artistic suggestiveness and reserve the fundamental disturbance in the hero's nature. He was radically ineffectual because the sexual fountain of power and interest in life was blocked and distorted from its true development. He was psychologically and physically incapable of giving to his first wife the love which her more healthy nature demanded. His imagined love for her was only a phantasied ideal as unreal as his dreamy enjoyment of all external beauty. His relation to his second wife was only the helpless reaction of a man utterly incapable of thinking or acting for himself, too ignorant of either his rights or his duties to avoid the marriage or to make something workable out of it once he had entered into the relationship. His attempts to set things right as well as he can are as infantile as all his actions. His clumsy, unsophisticated method of releasing his first wife from her marriage bonds brings upon him a seemingly undeserved nemesis in the venereal infection which later reappears twice in horrible form, first to mark another attempted sexual outbreak and then finally to ruin his second married life and precipitate his end. He has to learn that the race is not to the weak.

The book is a strong and fearless study of the inner nature of a man whose conscious ideals and good intentions could never have furnished explanation for his cumulative failure. Deeper study was necessary. The writer has multiplied the details of this failure somewhat unnecessarily. This seems to be a temptation to the modern analytical type of novelist. It will doubtless be easier in time to handle the vast field of unconscious motives more simply as readers and writers grow better acquainted with its features and mechanisms.

Physicians will recognize the clearcut clinical pictures of the symptoms of syphilis. As an object lesson in the dangers of venereal disease it is one of the most graphic stories that has ever been told. While it serves as a vehicle to convey the horrors and far-reaching effects of disease and portrays with clarity the follies and weaknesses of men and the webs of their own weaving into which they fall, it does not lose its artistic value at any part of the story.

HEREDITY AND ENVIRONMENT.

Heredity and Environment in the Development of Man. By EDWIN GRANT CONKLIN, Professor of Biology in Princeton University. Second Printing of Revised Third Edition. Illustrated. Princeton, N. J.: Princeton University Press; London: Humphrey Milford (Oxford University Press), 1920. Pp. xv-361.

A third edition of Conklin's lectures delivered at the Northwestern and Princeton universities presents the subject of the biology of the human race with its chief theme of heredity in a form enlarged and revised according to recent advance. This is an advance not only in biological investigation, affording therefore a wider and surer basis for the study of heredity and development, but represents also a growing and broadening interest in these problems. The latter is due in part to the growing

recognition of the interrelation of structure and function, upon which the writer lays emphasis. It rests also upon present greater surety in regard to the problems of heredity and its fundamental facts with realization of their importance in the understanding of the evolution and development of both mind and body. This means a possibility of control of man's development toward a better future physically and in all the departments of his psychic life. The author maintains throughout his discussions such an all embracing view reaching back through all development as well as forward through the present responsibility toward future improvement. He recognizes the unalterableness of heredity, the fixity of its principles and facts, and at the same time the influence in the unfolding of the race or of each individual in response to the stimuli of the environment.

He seeks to present practically and clearly the sociological implications of these facts, to present the dynamic relation of structure and function, as well as to make plain the facts of biology upon which all this rests as far as these facts have been discovered. He enters, therefore, with a simplicity and definiteness which make the book of practical value to every reader, into the subject of the factors and stages of development of the body, particularly of the germ cells, and of the mind in its parallel growth and development. Particular space is given to the discussion of heredity as it depends on these elementary facts of development and as it in itself forms a basis for all further development and conscious social effort toward improvement. The book is profusely illustrated by figures taken from the experimental work on germ cells and of human and other forms of life.

MODERN METHODS OF ANESTHESIA.

Handbook of Anesthetics. By J. STUART ROSS, M. B., Ch. B., F. R. C. S. E. With an Introduction by H. ALEXIS THOMSON, C. M. G., M. D., F. R. C. S. E., and Chapters upon Local and Spinal Anesthesia, by WILLIAM QUARRY WOOD, M. D., F. R. C. S. E., and upon Intratracheal Anesthesia, by H. TORRANCE THOMSON, M. D., F. R. C. S. E. Edinburgh: E. & S. Livingstone; New York: William Wood & Co., 1919. Pp. 214.

"This little book," says Ross in his preface, "is an attempt to present to the student and practitioner a condensed account of modern anesthetic views and practice." Let it be said at once that the attempt has been eminently successful. The first four chapters are devoted to the factors that modify the physiology of the patient during an operation under a general anesthetic. The author has very wisely refrained from describing in detail the technic of administering the volatile anesthetics and has limited himself to a consideration of the underlying principles. Throughout the volume emphasis has been laid on the relations of anesthesia to general medical science rather than upon elaborate descriptions of anesthetic apparatus which a few years hence may be superseded. The account of the use of nitrous oxide and oxygen is deservedly full, for a just appreciation of this mixture was arrived at through the experiences of the war. Gas and oxygen are the safest of all general anesthetics and for major operations should be preceded by a hypodermic injection of morphine

and atropine. During the latter part of the induction stage, it is well, especially for the tyro, to give a trace of ether vapor and to maintain it until the operation is well under way. Gas oxygen anesthesia is indicated in minor operations lasting five to fifteen minutes, particularly if performed on out patients; operations of any variety upon the subjects of severe shock; the removal of tonsils and adenoids, and may be employed as an adjuvant to gas or gas and oxygen and as a help to the speedy induction of closed ether. The discussion of the accidents and sequelæ of anesthesia is brief, lurid, helpful. In the chapter on choice of anesthetics Ross points out that the selection of the drug and the method depend on the age, sex, physical type, and temperament of the patient, the possible presence of some definite pathological lesion, and the nature and duration of the operation. Each of these factors is expounded so clearly that the selection of the proper anesthetic ought to be relatively easy. The chapter on local anesthesia was written by William Quarry Wood. "The section dealing with regional anesthesia will prove especially valuable to the surgeon. The chapter on spinal anesthesia, also contributed by Wood, leaves nothing to be desired. No one who has read this very valuable little volume can fail to agree with Alexis Thomson, who writes the introduction: "I feel on perfectly safe ground in recommending this book as . . . a reliable manual of instruction . . . to both the student and the practitioner."

THE SUPERJOURNALIST.

Woman Triumphant. By V. B. IBANEZ. Translated from the Spanish by HAYWARD KENISTON. With a Special Introductory Note by the Author. New York: E. P. Dutton and Company, 1920. Pp. v-322.

This novel has gone into fifteen editions in two months. That is its outstanding feature, and to one who does not take fifteen editions too seriously the fact is suggestive. It is singularly appropriate to Señor Ibanez's largeness of gesture, his fertility, the muscularity of his books. Any smaller circulation for such an expansive piece of writing would be like condemning a sunflower to a hotbed. We are glad the reading public has a sense of the fitness of things.

In telling this story the author invests with an air of romantic improbability events which are not entirely improbable. His main character is a figure greatly like himself—healthy, frank, theatrical, and objectively minded—a sort of superjournalist in painting. Mariano is deflected from artistic sincerity by his wife, who will neither allow herself to be painted nude nor permit her husband to use models. Ibanez does not quite dare to say that prudery and evasiveness are fatal to good painting of any kind, whether of the human body or of a collection of fruit. Paul Gauguin, who left his sympathetic, respectable wife to go to the South Sea Islands and paint, was aware of this truth. But Mariano Renovales does not do anything so indecorous. Instead he devotes himself to his wife, paints portraits of fashionable ladies with plenty of clothing, and earns a great deal of money. And most of the portraits are bad—Ibanez at least admits that.

Josephina, the wife, is left an invalid by the birth of a daughter, and the ugliness of ill health embitters both her life and that of Mariano. It is not surprising that the painter enters upon an affair with a woman as healthy as himself and that Josephina, discovering it, grows more hostile and bitter and ugly, finally dying of accumulated resentment. Here is where Señor Ibanez falls back upon one of those dexterous twists of the wrists which account for the fifteen editions. The Countess of Alberca, coming to reproach Mariano for his neglect, finds him "in love with his wife—and after she was dead! Shut up like a hermit in order to paint her with a beauty which she never had." "It is the wife who triumphs," comments our author in his preface, "resurrecting in spirit to exert an overwhelming influence over the life of a man who wished to live without her. . . . Renovales, the hero, is simply the personification of human desire, this poor desire which, in reality, does not know what it wants, eternally fickle and unsatisfied."

To Ibanez this character may be the personification of human desire, but to the reviewer he is a horrible example of what happens to those who temporize. Mariano sacrifices his art first to romantic love and second, when that love has vanished, to a sense of duty, and when he does break away it is not toward freedom but only to a hectic relationship with an indiscriminate woman. The outcome is the only possible one: Mariano at the end of his career is alone, his talent fading, and all that he has left is the delusion that he has always loved his wife and that she has always loved him! A more ironic situation could not be imagined, but the trouble is that Ibanez has taken it with entire seriousness as regards the external events and with a total want of psychological understanding. He has neither the sensuality of Mr. Robert W. Chambers nor the sentimental morality of Mr. Harold Bell Wright and he is less insular than either, yet he stands on the same plane. He writes astonishingly: the story is unfolded with an overflowing amplitude; the author has a detailed and dramatic knowledge of many sorts of human beings, and a seemingly endless store of energy with which to write about them. Nevertheless, his observation is essentially that of the journalist—alive to dramatic possibilities and the pageantry and color of life, recording itself with facility, and not concerned with what lies beneath the surface. He might in fact be called the superjournalist.

ADVENTURES IN SOUTH AMERICA.

The Purple Land. By W. H. HUDSON. Author of *Green Mansions*, etc. With an introductory note by THEODORE ROOSEVELT. New York: E. P. Dutton and Company, 1916. Pp. v-355.

The modern man, though he may now travel under or above the land, has little time to travel back to satisfy his curiosity concerning the beginnings of civilization and still less to dream of the possibilities of natural wealth in countries still not wholly known. What, then, should be known of the romance, the customs, the manners of those who inhabit them? Any encyclopedia will tell him that "The Purple Land" (Banda Oriental) was discovered by Magellan in 1500; and in 1515, Juan

Diaz da Solis, while searching for passage into the Great South Sea, entered the Rio de la Plata; that in 1535 Buenos Aires was founded, a city which, in conjunction with its own colony, Montevideo, virtually monopolized the history of a region equal in extent to Western Europe. It remains for the gentle but determined adventurer, the scientist, the novelist, and the poet to entrance our restlessness with the real story of a country.

So one is glad that W. H. Hudson gives us "The narrative of one Richard Lamb's Adventures in the Banda Oriental," glad that his book, first issued in 1885, has seen a new edition, for the disappointed stay-at-home traveler, the naturalist, and those who love stories of hairbreadth escapes, will find satisfaction and delight in sharing Richard Lamb's journey of perils and astonishments and learn with him the curious unwritten legends and stories in which the people delight. Those who know something of this vast country will recognize many places he mentions and the true portraiture he gives; those who hardly hope to go ajourneying will have their imagination so stimulated that pale thought will almost seem vital reality, even as it happened to the low salaried clerk, who at holiday time bought a railway guide and spent a few hours at a crowded London terminus. Imagination furnished the rest of the vacation.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

WHISPERS. By LOUIS DODGE. New York: Charles Scribner's Sons, 1920. Pp. i-261.

WARD TALES. By E. C. DAVIES, V. A. D. New York and London: John Lane Company, 1920. Pp. i-211.

JOAN OF THE ISLAND. By RALPH HENRY BARBOUR and H. P. HOLT. Boston: Small, Maynard & Co. Pp. i-292.

THE WHITE MOLL. By FRANK L. PACKARD, Author of *From Now On*, *The Night Operator*, etc. New York: G. H. Doran & Co. Pp. v-306.

Sixth Edition. Chicago: Chicago Medical Book Company, 1920. Pp. viii-1083.

Miscellany from Home and Foreign Journals

Thyroid Feeding Action on the Pancreas.—Hirotohi Hoshimoto (*Endocrinology*, January-March, 1920) says that nine normal male and five normal, nonpregnant female white rats were fed for several weeks on bread and milk. The diastase content of the pancreas varied (Wohlgemuth's method) from 25,000 to 35,000 units in males and 16,700 to 50,000 in females. The average for both sexes was 24,717. Feeding dry thyroid in doses of 0.5 to 0.1 gm. resulted in a marked decrease of the diastatic activity of the pancreas varying from forty to ninety-two per cent. This was accompanied by a diminution of the acidophile granules of the pancreas cells. Large doses of thyroid were more effective than small, but the effects in different animals were variable. The diastase content of the intestinal juice was also decreased in some cases by the thyroid. In such positive cases the appetite was markedly depressed and the feces were soft; in extreme cases they contained considerable quantities of fat. Thyroid feeding frequently resulted also in marked enlargement of the pancreas. In such cases the pancreatic diastase was often decreased even when the amount of food consumed and the intestinal diastase were augmented. The decrease cannot be ascribed to general metabolic perturbation since it frequently antedated any evidence of such: it is rather ascribed to stimulation of diastase discharge from the pancreas.

Intestinal Parasites in Filipino Children.—F. G. Haughwout and F. S. Horrilleno (*Philippine Journal of Science*, January, 1920) studied 100 sick Filipino children with regard to intestinal parasitism. Ninety-two per cent. were found infested with one or more parasites. Under one year the incidence was 66.6 per cent., and between the first and second years, 73.6 per cent. All the children between two and thirteen years were found parasitized. No protozoön of proved pathogenicity was, however, encountered in the series. It is suggested that an apparent immunity of children to forms such as *Entamoeba histolytica* and *Balantidium* may have a physiological basis in the child. The incidence of infection with *Spirochæta eurygyrata* was high—sixty-one per cent. The authors' experience coincides with that of other workers who have failed to record any definite train of symptoms attributable to intestinal parasites other than those that are specifically pathogenic. Concomitant infestation with *Trichuris* and *Ascaris*, however, is accompanied by an almost characteristic train of symptoms referable to the digestive tract. Combination of these two helminths is especially serious, the entire alimentary tract being involved. Children occasionally purge themselves of *Ascaris* infections, particularly if complicated by *Trichuris* infection, through vomiting or defecation of the worms, or both. Helminthal infections were restricted to the nematodes. Respiratory diseases other than tuberculosis, influenza, and pleurisy were met in thirty-three per cent. of the children studied. The lung stages of *Ascaris* may be responsible for much of the respiratory disease

among Filipino children. Hookworm infection was found in twelve per cent. of the series; only one severe case was recorded. Sanitary conditions are a heavy factor in the infection of children, but the weak link lies in the failure to educate mothers in the principles of domestic hygiene. A given city may be clean to educated people but insanitary with respect to the child. Campaigns through the schools, visiting nurses, and physicians should be instituted. Parasitism starts coincidentally with bottle or artificial feeding and even breast fed children do not escape in all cases. Intestinal parasitism contributes heavily toward the high death rate of young Filipino children. *Endolimax nana* and *Dientamoeba fragilis* are reported for the first time from the Philippine Islands. *Eutrichomastix* is provisionally reported.

Surgery of the Chest.—Berkeley Moynihan (*British Journal of Surgery*, April, 1920) gave the results of his experiences as follows: Forty-nine cases were treated by operation; two patients died, one from hemorrhage following the removal of a projectile from the root of the lung, and one from sepsis after the removal of an infected foreign body and a piece of clothing. The late history has been obtained in forty-three cases. Twenty-four patients are, they say, in perfect health, and are able to do heavy work. Fourteen of these patients are better than before operation, but still have some shortness of breath, or unusual respiratory trouble when having a cold, or in bad weather. Some are a little better since the operation. Two patients died; three are unable to do any work, or have serious respiratory trouble, shortness of breath, cough, etc. All but five were operated on by the ordinary anterior method. The five operated on by direct attack from behind show four with good ultimate results, one with fair result. Eighteen of the foreign bodies were examined bacteriologically; eleven were infected with *Staphylococcus aureus*, or *Streptococcus brevis* in equal numbers, or by these organisms together with coliform bacilli; seven were sterile. Empyema after operation developed in five cases, and in each of these, when the foreign body was examined, it was found to be infected. In twelve cases blood collected after operation in sufficient quantity to require aspiration. In all these the adhesions were dense, and were widely separated. These twelve include the five reported above in which empyema subsequently developed. Of the seven which did not suppurate, only once was the foreign body examined, and it was sterile. In ten cases the original injury had been followed by empyema. The only effect this had at the time of removing the foreign body was that adhesions were found to be very dense and extensive. Three cases were reported as having had hemothorax at the time of the original injury; at the operation for removing the foreign body, adhesions were dense; in two of these three cases an exceedingly thick blanketlike membrane had to be removed by scissors to allow the expansion of the lung.

Intussusception in Typhoid Fever.—A. L. Moreton (*British Journal of Surgery*, April, 1920) came to the following conclusions:

1. Acute intussusception is one of the rare abdominal complications of typhoid fever.

2. It may occur at any time during the progress of the disease, but usually late or during a relapse.

3. It may be caused by irregular peristalsis due to inflammatory changes in the wall of the gut, or an enlarged Peyer's patch may start the process of intussusception.

4. The intussusception is more commonly of the enterocolic type. If of the enteric type, there may be more than one lesion.

5. The differential diagnosis from perforation may be difficult.

6. The prognosis is good if the patient is submitted to operation, and the results of operative treatment are better than those of perforation.

7. In reducing the intussusception at operation, it should be borne in mind that diseased bowel is being dealt with, and that the utmost gentleness should be used in all manipulations.

Protein Sensitization in Bronchial Asthma and Hay Fever.—Charles N. Hensell (*Minnesota Medicine*, April, 1920) states that foreign proteins may enter the body chiefly through three different channels, i. e., inhalation, ingestion, and infection. In the inhalation type there are four sources, namely, 1, animal hair and dandruff; 2, pollens; 3, flour, and 4, dust. In the ingestion type there is but one source, namely, food. The chief food offenders in order of importance are, 1, cereals, such as wheat, corn, rice, rye; 2, eggs; 3, fish, such as lobster, salmon, mackerel, and cod; 4, casein; 5, beef; 6, chicken; 7, cocoa. Walker's proportion of the various causative factors is twenty per cent. sensitive to horse dandruff, fifteen per cent. to wheat, fifteen per cent. to staphylococcus pyogenes aureus, fifteen per cent. to early pollens, ten per cent. to late pollens, five per cent. to cat hair, three per cent. to staphylococcus pyogenes albus, and seventeen per cent. to miscellaneous proteins.

Distant Foci of Infection in Chronic Arthritis.—Herbert S. Chapman (*Annals of Surgery*, May, 1920) states that fifty per cent. of the cases of chronic arthritis treated at the Stanford University clinics by the removal of foci of infection, according to clinical observation, showed definite improvement. From personal observation of twenty-one cases, the following was concluded: Seventy-six and two tenths per cent. of the cases showed no definite improvement or change; four and eight tenths per cent. were worse after treatment. Although the proportion of improvement did not vary greatly in the different groups, the most striking results were obtained in those cases in which the focus was situated in the genitourinary tract. Long continued faithful treatment is necessary before improvement can be expected in the cases in which the focus is located in the genitourinary tract. Very rapid recovery with very few treatments was obtained in those cases in which the teeth were the seat of infection. Removal of the tonsils in several cases was followed in a few days by loss of pain, and later by return of function to the injured joint.

Pseudomyxoma Peritonei.—M. H. Biggs (*Annals of Surgery*, May, 1920) states that pseudomyxoma peritonei is much more frequent than is generally recognized. It is caused by cellular implantation. It is histologically benign, but may be clinically malignant. If it is considered to be a form of cancer, it must be assumed that pseudomucin inhibits its destructive power. It may originate in the ovary or the intestinal tract; ovarian origin being by far the most frequent. If it is appendiceal in origin, the appendix has been the seat of chronic inflammation. Early invasion of the peritoneum is characterized by a pebbly appearance. In early cases the condition will sometimes be cured, and at any stage it may be inhibited, by operation.

Operative Treatment of Vesicovaginal Fistulæ.—E. S. Judd (*Surgery, Gynecology and Obstetrics*, May, 1920) concludes as follows:

1. Vesicovaginal fistulæ are now more common following operations than following childbirth.

2. All vesicovaginal fistulæ should be considered operable as long as the sphincter muscle of the bladder is intact or can be repaired. If the sphincter has been completely destroyed it will be necessary to consider some other procedure.

3. Suprapubic extraperitoneal operations seem to be indicated if the cystoscopic examination reveals injury to a ureter as well as to the bladder, or it may be indicated if the fistulous tract is adherent to the pubic bone.

4. The plastic vaginal operation consists in completely separating the bladder from the vagina, and closing the two separately and obliterating all dead space.

5. A large proportion of complete and permanent cures follow such operations.

Suprapubic Prostatectomy.—J. W. Thomson Walker (*British Journal of Surgery*, April, 1920) in discussing prostatectomy presented the following findings in the operation he describes:

1. Two objections may be raised to this operation. It requires a longer incision than the usual prostatectomy, and more time is required for its performance.

2. The longer incision suggests the possibility of a hernia of the scar; but hernia depends upon the ability of the surgeon to repair the abdominal wall and to keep the wound clean.

3. The incision should heal up to the tube channel by first intention. With efficient repair of the abdominal wall, a hernia need not be feared.

4. The length of time spent on the operation from start to finish is about thirty minutes, and there is no increase in the shock after the operation. Shock in prostatectomy is partly due to hemorrhage and partly to rough handling in enucleation. Both of these causes can be avoided.

5. An unexpected feature of the open method is the absence of a great part of the spasmodic pain after operation. This pain, which lasts for twenty-four or forty-eight hours, is due partly to the large tube, but mostly to the accumulation of clots in the bladder, with consequent spasm of the bladder muscle in the attempt to expel them. The latter factor is abolished where the bleeding can be efficiently combated.

AN EFFORT TO STANDARDIZE SURGICAL MENSURATION.*

BY R. TUNSTALL TAYLOR, M. D., F.A.C.S.,
Baltimore,

Late Lieutenant Colonel, M. C., U. S. Army, and Chief of Orthopedic Service, U. S. Army General Hospital No. 2, Fort McHenry, Maryland.

Many different methods have been suggested for making measurements for both military and civilian clinical records, and it is with a desire of obtaining a standardization of these that the present paper is concerned, as well as to encourage recording by a simple method. In the majority of hospitals, no measured record of affected bones and joints is kept. In these hospitals the only instruments for routine anthropometric record are usually the tape-measure, the x ray and possibly the photographic camera. In a small number of hospitals, chiefly orthopedic, an endless number of devices are to be found, many inaccurate and unscientific, for measuring the range of motion or angle in joints. It can almost literally be said that no two of them use the same appliance for recording motion and each has a different apparatus for each joint in the body.

It is conceded that for the most thorough work, full bedside clinical records should be detailed on the chart, not only to give data as to the condition of a patient when first seen, but also to note progress under treatment and the end result. In the standardization of hospitals, proposed by the American College of Surgeons, full clinical records are insisted on.

It is advisable that any device adopted for recording motion should be of universal application to all joints to render use general, and not require one for each joint. The device should be simple in construction, inexpensive, and easy to use, so that the readings of different individuals should give minimum variations in the hands of the different observers, and thus the personal equation be eliminated, as far as possible.

RECORDS REQUIRED.

Three and possibly four comparative records are required in the involved and uninvolved extremities and joints on the two sides, viz: a, length of extremities; b, circumference of extremities; c, motion of each joint; d, position of angle of malposition in ankylosis or partial ankylosis. In the spine, deviations in an anteroposterior or lateral direction and

limitation of motion in the different regions are to be recorded as to extent. The amount of rotation in scoliosis, as to degrees, is necessary for record.

It is essential for accuracy that a fixed position of the body be maintained for immediate and future observations. This can only be attained when the body is supine or prone, centred on a horizontal examining table with the extremities symmetrically placed, unless the disability itself prevents, except in pronation and supination of the forearm and motions at carpus metacarpophalangeal and interphalangeal joints. In a standing attitude a patient may consciously and intentionally or unconsciously tilt or lean forward, backward, sideways or in a twisted position and no records at stated intervals should be made thus with any idea of accuracy.

APPARATUS REQUIRED.

1. Table. An ordinary horizontal rectangular wooden top examining table, six feet, six inches long and three feet wide with legs three feet high is necessary. The centre of this table at top and bottom is marked with a thumb tack. An imaginary line joining these will constitute what we may call our base line. In the region that will correspond with the location of shoulder and hips of patients to be measured, two lines are ruled on each side parallel with the table's edge, and, of course, with the base line and three inches apart. These we speak of as parallel lines. (See Figure 1).

We know from geometry that when a line crosses two parallel lines, the alternate interior angles are equal and any line at right angles to the first line crossing the parallel lines produces also alternate interior equal angles. (See Figures 2 and 3).

Therefore, any angle made by an extremity in relation to the base line or upon which we have the axis of the patient's body or a joint resting, is identical with that angle obtained from the table's edge or any line parallel to it, when the patient is properly centred. Take for example, adduction of the humerus. (See Figure 4). AB equals the line of axis of humerus. The angles BGH and BFD are not measurable as the patient is lying on them, but the angle ECA (or BCJ) is identical and equal to them, easily sighted and accessible. (See Figure 4). It would be manifestly incorrect to put any instrument on top of the rounded shoulder or hip, and expect to obtain an accurate reading. These readings, however, from the parallel lines are readily made by a graduated semicircle and protractor.

*Published by permission of the Surgeon General, U. S. Army.

2. The semicircle with a protractor at its centre made in our orthopedic shop at Fort McHenry is graduated in degrees to measure the range of motion. This is made of aluminum, and has two forklike legs, which may be attached, if it is desired to use it vertically, as well as horizontally without them.

3. The ordinary cotton spring tape measure. This is preferable to the steel tape measure, as will be

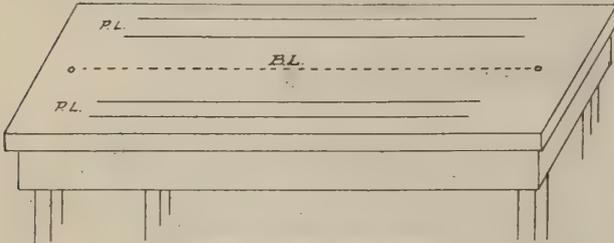

FIG. 1.—Examining Table

seen under measurement of circumference. (Figure 5).

4. The lead tape consists of a strip of sheet lead three mm. thick, two cm. wide and one metre long, and is to be molded over curves and used then as a ruler to trace these data on the history. (Figure 6).

5. A rectangular drawing triangle.

6. A yard stick.

STANDARD POSITIONS OF PATIENTS TO BE MEASURED.

In order that all subsequent measurements may be comparative, it is essential that a standard position be agreed upon in which all individuals are measured and as in all upright positions, inclination of the trunk in relation to itself or to the extremities are likely to vary, the position in recumbency becomes the natural standard. The centre of the table in the region of the head and the heels is used as the guide in placing the patient in the supine or prone position. The arms are to be at the sides, fully extended, and the forearms in neither pronation nor supination, and the fingers fully extended.

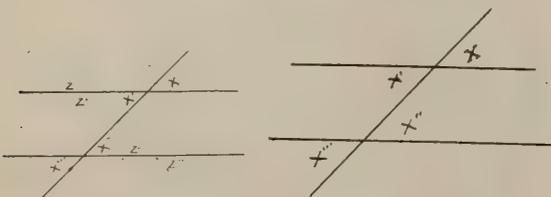

FIG. 2. FIG. 3.

Geometric figures used as a basis for making the records.

The line joining the anterior superior spines of the patient must be at right angles with the base line. The legs are fully extended with the toes pointed vertically upward, and the heels equally distant from the central base line.

For records of spinal deviation or knee flexion, the patient is similarly to be centred in the prone position. The recording angle of rotation in scoliosis is demonstrated by yard stick and graduated

semicircle and protractor. Figure 6 shows the recording angular deformity in Pott's disease by the lead tape, which is to be used as a ruler in tracing curve on the history. Figure 7 shows method of recording flexion of knee. A method is demonstrated of measuring by means of yardstick and

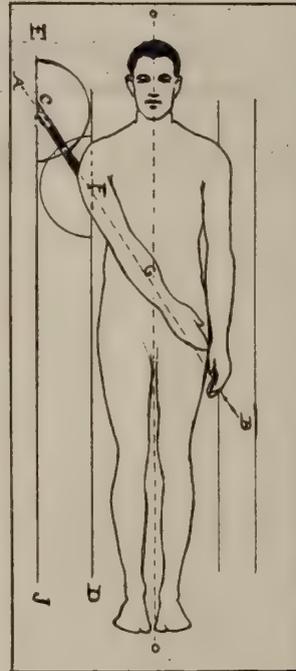

FIG. 4.

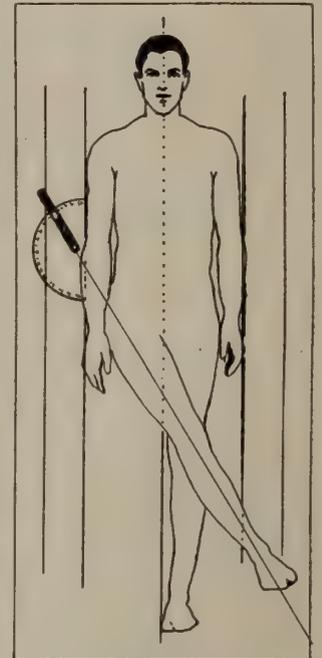

FIG. 5.

The readings are determined by the parallel lines made by a graduated semicircle and protractor.

rectangular triangle amount of deviation of spine from base line in lateral curvature. For records of pronation and supination of the arm and flexion of the metacarpophalangeal joints and wrist, the patient sits beside the table with the entire forearm supported. (See Figure 8). For tests of flexion of terminal phalanges or second joints

FIG. 6.—The lead tape being molded over curves.

the palm surface of the hand is placed on the table up to the joint and the reading made.

LANDMARKS.

The following landmarks are, as a rule, easily and accurately located in all individuals in order to

measure length of bones: 1, Suprasternal notch; 2, tip of the xiphoid cartilage; 3, symphysis pubis; 4, anterior superior spines; 5, anterior tibial tubercles; 6, malleoli; 7, acromion processes; 8, olecranon processes; 9, styloid processes of the ulnæ; 10, vertebra prominens; 11, posterior superior spines; 12,

FIG. 7.—Method for recording flexion of the knee.

ischial tuberosities; 13, greater trochanters, and 14, gluteal notch.

When the patient is in position, 1, 2 and 3 are on the base line, and the line joining the two anterior superior spines should be at right angles to the base line. The distance from the anterior superior spine to the internal malleolus on each side gives the comparative measurement of the two legs. If one is found shorter than the other, and it is desired to determine the bone at fault, this may be done by measuring from the anterior superior spine to the anterior tibial tubercle and from there to the malleolus on each side.

Similarly the arms may be measured from the acromion processes to the styloid processes of the ulnæ, and to and from the olecranons.

The anterior superior spine, the greater trochanter and the ischial tuberosity are normally on Nelaton's line. Departure of the trochanter from this line indicates dislocation or fracture or bending of the femoral neck of so much displacement, depending on the amount of this departure. This is an accepted measurement for record.

The vertebra prominens, the spine and the gluteal notch in the normal prone individual constitute a straight line parallel to our base line. Departures laterally to one or the other or both sides consti-

tute a lateral curvature, and backward or forward, an anteroposterior curvature, and must be measured as must be rotations or twists in the spine in the cervical, dorsal or lumbar regions. (See Figure 6).

COMPARATIVE MEASUREMENT OF LENGTH OF LIMBS.

After accurately marking the landmarks needed with ink or skin pencil, it is quite easy to measure the lengths desired. It is better not to press the scale of the tape measure on the skin, as the latter is likely to slip, but simply place the scale lightly on the parts and make the reading.

Major Robert D. Maddox, M. C., U. S. Army, suggested that the tape be stretched tight beyond the two points, with the figure 10 at the first point and the number noted at the other fixed point, when the reading could be recorded less 10. This would obviate error from undue or unequal stretching of the tape or slipping of the skin.

COMPARATIVE MEASUREMENT OF CIRCUMFERENCE OF LIMBS.

It can easily be appreciated that owing to the conical shape of limbs, circumferential measurements must vary considerably, if made at different levels; it is essential, therefore, that identical points be chosen on the two limbs for comparison, and these points should be marked with ink or skin pencil at a measured distance below a fixed bony landmark. Thus in the thighs the points chosen should be a

FIG. 8.—Method of securing readings of wrist flexion with entire forearm supported.

given number of inches or cms. below the anterior superior spines; in the calves, below the anterior tibial tubercles; in the arms, below the acromions; and in the forearms, below the olecranons. Major Maddox also suggested that in order to get even tension on the tape that the free end be held in one hand, then the part be encircled and the tape case

be allowed to fall vertically as a plumb bob. The number 10 is used as the first point, and where the tape passes the 10 after encircling, is read and recorded less 10.

MEASUREMENT OF ANGLES OF POSITION OR RANGE OF MOTION IN JOINTS.

The desire to record these observations on charts has led in private practice and hospitals, where a

FIG. 9.—Method of recording dorsal flexion at the ankle joint.

sincere effort has been made to keep accurate progress charts, to an endless number of complicated and expensive appliances. Many records were inaccurate, owing to the necessity of application to the patient when the latter was in what might be termed an unstable position, or one in which from time to time, or one may even say from one minute to the next, variations in readings might be observed with proportionate errors. It is therefore essential to accuracy that the positions described above be insisted on, and all measurements of angles be made with relation to the base line or one of its parallel lines on the horizontal table.

It is further important that all readings of the position of extremities or their components be made from a zero position, i. e., neither flexed nor extended, rotated in nor out, pronated or supinated, etc. It is necessary for this basis to be agreed on in comparing results in different clinics. For example, it is manifestly confusing for an author to speak of flexion of the elbow of 70° , when he means 110° , that is, starting from zero or full extension. Similarly semipronation should be pronation of 90° , or supination of 90° .

It is therefore patent, I believe, that the method herewith introduced is accurate to all intents and purposes, sound, practical and simple, and may be applied to all the joints with but slight, if any, different findings, if obtained by different observers. This we have proved to our satisfaction by testing the findings of several assistants seriatim and comparing the very negligible error.

Figure 5 shows the recording of adduction of the hip joint, and Figure 9, recording dorsal flexion at the ankle joint.

1102 NORTH CHARLES STREET.

DIAGNOSTIC TESTS IN HAY FEVER AND ASTHMA.

By WILLIAM SCHEPPEGRELL, A. M., M. D.,
New Orleans,

President, American Hay Fever Prevention Association; Ex-President, American Academy of Ophthalmology and Otolaryngology; Chief of Hay Fever Clinic, Charity Hospital.

As the immunizing methods of treating hay fever and hay fever asthma are becoming recognized as the most practical means of controlling these diseases, it is important that accurate methods be employed in order to obtain successful results.

GEOGRAPHICAL DISTRIBUTION.

In the majority of diseases, such as smallpox, diphtheria and tuberculosis, the causative factor is a pathogenic microorganism, which is the same regardless of the geographical distribution of the disease. In hay fever, however, in spite of the apparent similarity of the symptoms, the cause is a pollen which varies materially in different locations. In Europe, for instance, the cause of hay fever is the pollen of the grasses, Gramineæ, to the exclusion of the ragweed (Ambrosiaceæ) group. In the United States, however, while the grass pollen is the most common cause of spring hay fever (sometimes erroneously called rose cold), the pollens of the ragweed group form the principal cause of fall

FIG. 1.—The grasses, Gramineæ group, form the principal cause of spring summer hay fever in Europe and most sections of the United States. The illustration shows the following grasses: Meadow, redtop, timothy, perennial rye, orchard, foxtail and Johnson.

hay fever (1). In view of this, it is important, before commencing immunizing methods, to determine the incriminating pollens; or, what is usually sufficient and more practical, the group to which biologically the pollen belongs.

BIOLOGICAL GROUPS.

From the viewpoint of immunization, we have divided the principal hay fever pollens into four groups, which include eighty-five per cent. of all hay fever pollens. These groups are as follows (2):

1. Gramineæ (Fig. 1). All species and families

FIG. 2.—Marsh elder, *Iva ciliata*, belonging to the ragweed (Ambrosiaceæ) group. Found in moist soil, Illinois to Nebraska, south to Louisiana and New Mexico.

of the grasses, including the cultivated varieties (cereals).

2. Ambrosiaceæ (Fig. 2). This includes the various varieties of ragweeds, Ambrosias, cockle burs, *Xanthium*, marsh elders, *Iva*, and false ragweeds, *Gærtnerias*.

3. Artemisias (Fig. 3). The wormwoods, of which there are about sixty species in the western parts of North America, and which are important factors in hay fever in the Pacific and Rocky Mountain States.

4. Chenopodiaceæ (Fig. 4). This group includes the chenopods, docks, *Rumex*, amaranths, *Amaranthus*, and Russian thistle, *Salsola pestifer* and *glauca*, which, although botanically not as closely related as the three other groups, are similar in their hay fever reaction.

In the application of pollen therapy, the extracts of the pollens of any one of these groups are interchangeable, and may be used singly, or a combination of several, for testing and immunizing methods. As an indication of the more scientific methods in the treatment of hay fever demanded by the medical profession, the majority of the biological houses now prepare these pollen extracts of single pollens,

or of the same biological group, instead of the shotgun method formerly in vogue, in which many kinds of pollen, and belonging to different biological groups, as the grasses and ragweeds, were used, and recommended for immunizing purposes.

ATMOSPHERIC POLLENS.

An important feature, which seems not yet well recognized, is the fact that hay fever is due to atmospheric pollens, and that only these are needed for testing and immunizing purposes (3). We are still receiving frequent inquiries regarding such plants as clover, daisies, golden rod, oleanders and jasmines, as a cause of hay fever, and these are still referred to as furnishing hay fever pollens, in otherwise excellent articles published in the medical journals. The persistence of placing blame on the golden rod is especially remarkable, in view of the well known fact that the most brilliant bloom of the golden rod, *Solidago canadensis*, is in October, when practically all of the hay fever attacks have subsided by the end of September (4).

DIAGNOSTIC TESTS.

In making the diagnostic test for hay fever, we are guided, in the selection of the pollen extract, by the location. It is therefore necessary to know the hay fever plants to which the patient is exposed, the representative biological group being sufficient in most cases. East of the hundredth meridian, we

FIG. 3.—Wormwood sage, *Artemisia frigida*, artemisia group. On dry plains and on rocky soil, Minnesota to Saskatchewan, Yukon, Idaho, Nebraska, Texas and Arizona.

must test for the grasses, ragweeds and chenopods. West of this meridian, the tests should in addition include the artemisias. The ragweed test should also be made in the Rocky Mountain and Pacific

States, since, although the ragweeds are uncommon, there are other members of the ragweed or Ambrosiaceæ group, such as the gærtnerias, marsh elders, Iva, and cockle burs, which respond to the same test and similar immunizing methods.

In making the diagnostic test, we have standard-

FIG. 4.—Curly dock, *Rumex crispus*, Chenopodiaceæ group. Found throughout the United States and Southern British America.

ized the method, which, in a series of over a thousand cases, has given us results which are accurate as regards the nature and degree of the sensitization, and reliable as a guide to the immunizing doses. Five units of the extract of the selected pollen, of the strength of one hundred units to the c.c., are injected into the skin, and the reaction determined

FIG. 5.—False wormwood, *Parthenium hysterophorus*. From southern Pennsylvania to Illinois, Missouri, Florida and Texas, and throughout tropical America. In warm climates, the parthenium blooms every month, and is a minor cause of perennial hay fever.

in twenty minutes, and recorded on a percentage basis. A marked wheal, two or more centimetres in diameter, is recorded as one hundred per cent., one centimetre fifty per cent., etc. While this is

an arbitrary scale, it is valuable for gauging the size of the dose and for purposes of comparison, and is much more definite than such terms as mild, marked or severe.

TESTS AS A GUIDE TO DOSE.

The record of the diagnostic test is placed at the head of the clinical chart for each patient, so as to form a constant guide in administering the immunizing doses. A mild reaction indicates a proportionate tolerance of the pollen extract, and a marked reaction that caution should be used in increasing the doses of the pollen extracts. In one of our patients, whose test is registered ninety-five per cent., the limit of his dose is one hundred and seventy-five units of ragweed pollen extract. As soon as this dose is exceeded, a miliary eruption develops and sometimes a typical hay fever reaction.

The record of the test also indicates the probable maximum dose required for desensitization. In patients of ninety per cent. reaction or over, two hundred units is the maximum dose, and should be reached by gradually increasing doses. In those

FIG. 6.—Flowers (florescence) of marsh elder, showing enormous pollen production of wind pollinated plants.

marked sixty per cent. the maximum dose is six hundred units, and others in proportion (5).

TESTS FOR PATHOGENIC GROUPS.

In our last series of cases, in addition to the tests for sensitization to the various groups of pollens to which the patient is exposed, we include the test for a vaccine composed of the following microorganisms: *Bacillus Friedlander*, *Micrococcus cattarrhalis*, pneumococcus, *Streptococcus pyogenes*, *Staphylococcus aureus* and *albus*. If there is a marked reaction to the intradermal injection of this vaccine, it is used as a part of the immunizing process, and the degree of the reaction, as in the case of the pollen extracts, forms a guide to the size of the injections.

IMPORTANCE OF ACCURATE TESTS.

We believe that the relatively high degree of success in the treatment of hay fever in our hay fever clinic at the Charity Hospital (6) is due to the fact that each case is individualized, and a course of treatment followed that is based on the character

and degree of the diagnostic test, and regulated by the records of the atmospheric pollen plates and the reaction of the patient. To inject large doses of extract in order to immunize a patient, when he is already absorbing the protein of numerous atmospheric pollens, tends to develop an anaphylactic shock that explains many failures in the treatment of these cases.

Naturally, this is avoided if the immunizing is commenced before the attack is due. Unfortunately, however, the majority of patients apply for treatment only when they are already suffering from hay fever. This complication requires much greater delicacy in the application of the treatment; but, unless due attention is given to these details, the results will be discouraging to the physician and disappointing to his patient.

A REPORT OF SOME INTERESTING CASES OF PROTEIN SENSITIZATION.

By MAXIMILIAN A. RAMIREZ, M. D.,
New York,

Associate Attending Physician to the French Hospital, Assistant Attending Physician to City Hospital.

CASE I.—A. J., female, aged thirty-six, married. Family history: Father has chronic asthma, otherwise negative. Previous history: Has had several attacks similar to present illness, lasting two to three weeks. Present history: The attack began four days ago with severe pain in the right eye. The eye became very red. Examination established the diagnosis of a definite scleritis of an unknown etiology. Patient had been taking salicylates and colchicum without any relief. A protein test was performed and a positive three plus reaction to white of egg was obtained. The patient was instructed to abstain from taking white of egg in any form; all other medication was discontinued. Three days later she returned feeling perfectly well. There was no pain and the eye was absolutely normal.

I believe this to be a true case of protein sensibility in view of the previous history in which we note the long duration of previous attacks, the lack of relief under large doses of salicylates and the rapid improvement after removal of a protein which gave a definite skin reaction. I have tested three other cases of scleritis giving positive skin tests and recovering rapidly after removal of the offending protein.

CASE II.—Female, aged twenty-seven; family

history and previous history negative. Present history: The difficulty began eight days ago with itching and burning of right eye, profuse lachrymation, marked photophobia and intense redness of palpebral and ocular conjunctiva. The patient had been receiving local treatment for the eye without apparent relief. A protein test performed on the ninth day of her illness showed a positive reaction to mustard, wheat and crab, of which the patient had partaken freely for several days preceding the present attack. The diagnosis was an acute conjunctivitis of anaphylactic origin. On removal of the offending proteins the conjunctivitis rapidly subsided and within three days the eye was absolutely normal.

CASE III.—L. H., female, aged forty. Family history, negative. During the past few years the patient had had repeated attacks of sudden decided swelling of lips and tongue during or immediately following a meal. Examination showed the lower lip, gums, tongue and soft palate to be markedly swollen and edematous. A diagnosis of angioneurotic edema was made. The protein test showed a very marked reaction to white of egg. The reaction measured two cm. in diameter. The patient was desensitized against white of egg and can now take one egg a day without symptoms appearing.

CASE IV.—B. McG., aged seven. Had had severe attacks of bronchial asthma for two years, especially severe during the summer months. The family history was negative; physical examination, negative. The protein test showed a positive reaction to potato, white of egg and rabbit hair. The patient had two rabbits in the house. Removal of the potato and white of egg from the diet and removal of the rabbits resulted in a complete recovery in several days. The patient has not had an attack of asthma in seven months and skin tests with potato, egg white and rabbit hair are now negative.

CASE V.—L. K., aged ten. Had had asthma for two years with persistent cough and expectoration. Physical examination showed the presence of a chronic bronchitis. The protein test gave a positive reaction to banana, potato and chicken. Also positive to parrot feathers, *Staphylococcus aureus* and slightly positive to goose feathers. The offending proteins were removed from the diet, the parrot was disposed of and a suitable *Staphylococcus aureus* vaccine injected by Dr. L. B. MacKenzie, who referred this patient for protein examination. The patient has made a complete recovery and is now absolutely free from asthmatic symptoms.

CASE VI.—A. B., aged forty-seven. Persistent asthmatic attacks every night for past six years; could not lie in bed at night; free of symptoms during the day. Protein tests showed a strongly positive reaction to goose feathers. Patient has been free of all symptoms since the substitution of a hair pillow, and is sleeping comfortably in bed all night.

CASE VII.—J. V., aged seven. Complained of repeated attacks of severe epigastric pain. Pain came on three to four hours after eating and lasted for about thirty minutes. Duration of present illness about six months. The previous history was

negative; the physical examination was negative. Gastric analysis showed free hydrochloric acid, 40; total, 70; blood negative. X ray examination showed a decided pylorospasm. Negative for ulcer of stomach, colon and pathological gallbladder condition. Protein test showed a strongly positive reaction to whole egg. All egg was removed from diet and patient has only had an occasional attack of pain since day of testing, four months ago.

I believe these occasional attacks were due to the presence of some egg in his food. Skin test four months later still gave a slightly positive reaction. I have seen four cases of pylorospasm with moderate increase in gastric acidity of definite anaphylactic origin in which the spasm completely disappeared on removal of the offending protein. Two of these cases were in children under ten, and the other two in adults over twenty.

CASE VIII.—Rev. H. G., aged twenty-seven. Severe dermatitis extending over both hands and arms. Family history, mother has had hay fever for twenty years. Previous history, hay fever coming on about August 20th for past six years. Had never had a skin eruption before present illness, and never had hay fever, except after middle of August. The present illness began two weeks ago (May 5, 1919), with burning and itching of both hands and arms and the appearance of the eruption, which was characteristic of dermatitis, followed in two days by an attack of hay fever. The protein tests gave a negative reaction to all the common foods, bacteria and animal emanations, but gave a four plus to ragweed and three plus to timothy, and two plus to sunflower. Believing that the dermatitis was due to timothy sensitization, and it already being the timothy pollen season, I advised this patient to go on a sea trip, as it was too late to obtain beneficial results from active immunization. A few days after leaving on this sea voyage the dermatitis disappeared completely. The patient returned to me in June for immunization against ragweed and sunflower, free from all signs of the previous attack of dermatitis.

2 WEST EIGHTY-EIGHTH STREET.

PEPTIC ULCER.

Clinically and Röntgenologically Considered.

BY JOSEPH S. DIAMOND, M. D.,

New York,

Associate Röntgenologist, Beth Israel Hospital.

(Concluded from page 91)

Mobility and flexibility.—The supporting anchorage of the stomach are the esophagus and the gastrophrenic ligament at the cardiac region and the duodenohepatic ligament about one inch beyond the pylorus. Between these parts the body of the stomach has considerable range of movement and by palpation can be lifted or shifted to either side. It moves with respiration. By forcibly contracting the abdominal muscles it can be drawn upward distorting its outline. If the abdomen is relaxed the gastric walls are flexible and can be indented on palpation.

Gastric secretions.—In the normal stomach the fasting secretions are negligible and cannot ordinarily be seen unless under pathological conditions.

Peristalsis.—Considerable attention has been devoted to gastric peristalsis. The ringlike contraction waves passing over the stomach at definite intervals represents its physiological motor phenomenon of churning of the food and its expulsion into the duodenum. Viewed fluoroscopically we notice an initial contraction, soon after the introduction of the meal, best seen after a sediment mixture consisting of barium and water. This appears as an indentation on the lesser curvature in the vestibule just below the incisura angularis. Simultaneously there appears a corresponding wave at the greater curvature. These are of short duration. If the full meal is now administered, there occurs a delay of from about five to ten minutes during which time no peristaltic contractions are seen, due to the sudden distention of the muscular walls. Soon, however, the regular peristaltic contraction sets in. A shallow wave first appears on the greater curvature below the level of the incisura cardiaca in the pars media. A wave similarly shallow but even less perceptible is seen on the lesser curvature. They travel down gathering but little in depth until they reach a point just beyond the incisura angularis, when the waves suddenly increase in depth, the contractions producing the maximum indentations in the vestibule or antrum pylori, from whence they travel sharply toward the pylorus. At times the depth of the wave is so intense that the stomach appears to be divided into two parts. This has aroused considerable discussion in the past as there was believed to exist a sphincter antri separating the stomach into two compartments. By the animal experimentations of Cannon and the bioröntgenographic studies of Rieder, Kaestle, and Rosenthal, it has been definitely proved that there is no cleavage of the stomach. Cannon explains these augmented contractions as the necessary requisite for the churning and chymification of the food. The energy of the wave varies with the type of stomach, being greatest in the hypertonic and orthotonic stomachs and less in the subtonic types. It is influenced by the deep respiratory movements and by abdominal massage and is greater in the prone and oblique postures. The waves succeed each other at regular intervals, the traversing of each wave throughout the entire length of the stomach consumes about twenty-two seconds and is spoken of by Cole as a gastric cycle. Several waves are often seen simultaneously and are spoken of as the one, two, three, or four cycle stomach.

Motility.—It is an established fact that the röntgenological examination offers conclusive evidence of gastric motility. The findings in a given case are taken as a definite index of the power of the stomach to empty itself within normal or abnormal limits. When a definite standard of meal is used, the carbohydrate (Rieder) meal or its modifications, it has been found that the longest time for a normal stomach to empty itself is six hours. The steer-horn stomach empties sooner, between two and a half to three hours. The orthotonic type empties between four and five hours and for the subtonic

types six hours are allotted. In the Haudeck hubhöhe or the Satterlee and Le Wald water trap stomachs, which are nothing but markedly exaggerated subtonic stomachs with the acute incisura angularis, the pylorus rising sharply upward, a longer time than six hours is required. Eight hours may still be considered normal. If it exceeds this period we must regard the condition as pathological. Carmen and Miller in a series of 950 cases at the Mayo clinic, which were examined by means of both the röntgen rays and the test meal, and went to operations, state: "Our own series indicates the six hour bariumized carbohydrate meal is a more sensitive test of gastric motility than the method

tion and depth. According to location we may consider: 1, Ulcers on or about the lesser curvature (on the posterior and anterior walls approximating the lesser curvature); 2, pyloric ulcers in the prepyloric region; 3, ulcers situated at the cardia. Classified according to depth: 1, Mucous or simple ulcers involving the superficial layers; 2, penetrating or callous ulcers, when the ulcer is of long standing and has ulcerated into the deeper strata of the muscular walls producing deep craters, spoken of also as saddle ulcers when overriding the lesser curvature; 3, perforating ulcer, the ulcer extending outside the stomach walls beyond the visceral coat forming at times an accessory pocket in the surrounding tissue.

The röntgen methods of diagnosis of gastric ulcer are as follows: 1, Direct method, which consists of the visualization of the niche, accessory pockets and pyloric craters; 2, indirect method, consisting of secondary or contributory signs indicating the departure from the normal morphology and from the normal physiological function, plus the appearance of adventitious signs which give expression to the disturbed functions.

DIRECT SIGNS.

Penetrating ulcer (Haudeck niche), Fig. 1, on the lesser curvature is seen as a forward projection from the contour of the stomach appearing as if it were a diverticulum filled with barium. It is best seen when situated above the incisura angularis. It varies in size and shape; usually rounded in outline, it may assume any irregular form. The size varies according to the depth of the penetration, from a few mm. to an inch or more. When on the posterior or anterior wall it is best seen when using the sediment mixture. At times it may be completely missed when the buttermilk mixture is at once administered. I have had many opportunities to verify this and use the sediment mixture to good advantage. All positions must be utilized, especially both obliques.

2. The perforating ulcer with the accessory pocket shows the diverticulum with a supervening layer of air simulating a miniature stomach pouch. Here the base of the ulcer has gradually perforated through the visceral layer of the peritoneum into the neighboring organs such as the pancreas or liver, becoming firmly adherent. The niche with the accessory air pocket is often seen after the stomach has completely emptied itself. A niche must be differentiated from a filled loop of small intestine, usually the duodenojejunal junction jutting above the gastric line; also from an apparent elevation on the gastric walls intervening between two closely following peristaltic waves. Both of these waves, while persisting for a time, are not constant. The differentiation will be made fluoroscopically.

3. Callous ulcer of the pylorus when occurring close to the pyloric sphincter gives the appearance of a filling defect and not as a projection. When of long standing it may simulate an early carcinoma defect. Fig. 8 illustrates the persistent filling defect of a callous ulcer about half an inch away from the pyloric sphincter as seen in the multigraph exposure. The case was one of extreme interest. It occurred

FIG. 1.—Large penetrating ulcer on the lesser curvature. The deep forward projection from the lesser curvature simulating a diverticulum shown.

used by the gastroenterologist." The röntgen ray showed approximately seventy per cent. more retention in pathological cases than the clinical methods of extraction about fourteen hours after a Riegel meal and raisins partaken the night before.

In taking up the röntgen interpretation of peptic ulcer we shall consider them in the two main classifications: Gastric and duodenal ulcers.

Gastric ulcer.—The accuracy of the röntgen diagnosis of gastric ulcer today cannot be overemphasized. Carman and Miller state: "From our statistics we can say that nine tenths of the ulcers of the stomach give distinct röntgenological indications of gastric disease, and in an overwhelming majority of these the signs are either pathognomonic or strongly presumptive."

Gastric ulcers may be classified according to loca-

in a young woman about twenty-eight years of age with gastric symptoms of rather short duration, in whom a fairly large tender mass was felt extending downward toward the right iliac region. The clinical diagnosis was that of a possible hypernephroma. The röntgenological examination at once

FIG. 2.—Organic hourglass stomach of several years' duration following penetrating ulcer of the lesser curvature. Large doses of belladonna left condition unchanged.

made the diagnosis of callous ulcer of the pylorus with pyloric stenosis. Operation corroborated the diagnosis. The mass which was nothing but a large inflammatory exudate disappeared shortly after the gastroenterostomy operation.

INDIRECT METHOD.

The secondary or contributory manifestations of gastric ulcer will be more easily understood if we consider the same phenomena governing the normal stomach, such as the type, tonus, outline, motility and peristalsis, and how they are influenced in the pathological states. In addition several new factors make their appearance—the so-called spastic manifestations.

Hyperacidity and hypersecretion are the main functional disturbances in ulcer. A study of the röntgenological appearance of these functional changes and of their influence upon the stomach constitutes the indirect method of interpretation. These changes are differently expressed, depending upon the location of the ulcer and the underlying type of stomach. In speaking of the normal stomach, stress was laid upon the relation of the morphology of the stomach to the status of the individual. In diseased conditions, however, the relation becomes disturbed so that an individual normally the possessor of a subtonic stomach may have a hypertonic stomach, and vice versa. The alterations

in form are due to changes in the tone of the musculature of the stomach in response to the stimulus of an existing lesion. The changes thus wrought will vary with the location and duration of the ulcer. There may also occur alterations in size, capacity and position, the stomach rising higher within the abdomen or descending lower. Similarly there may occur disturbances in the motor phenomena, as seen by the changes in the peristalsis and motility of the stomach. Changes in outline are likewise encountered, resulting from increased muscular irritability, which distort the contour diffusely or specifically. These functional changes in outline are spoken of as spasm, and the stomach may assume either the hourglass form or may be diffusely distorted. Organic changes arising from connective tissue infiltrations around ulcer areas will cause adhesions and will anchor the stomach in abnormal shapes and positions, such as is seen in the snail form, or organic hourglass (Fig. 2). Pressure from without, such as gas in the splenic colon, enlarged spleen, and tumors may likewise produce distortion in outline.

Tone.—In gastric ulcer loss of tone is the rule. When situated at the lesser curvature the hypotonic or stretched out fishhook type is invariably encountered. In the administration of the meal, while there may be a temporary delay at the site of the ulcer, it soon, however, is seen to drop into the lower gastric pole, which appears distended and sagging. In pyloric ulcer with long continued obstruction the loss of tone is considerable and all the muscle fibres are stretched out, the stomach appearing uniformly enlarged, taking on the appearance of ectasia. The upper as well as the lower gastric pole and pylorus are uniformly widened.

Peristalsis.—Altered peristalsis is not an outstanding feature of ulcer situated in the pars media. Pyloric ulcers, however, when associated with various degrees of stenosis, exhibit an increase in depth and number of the waves. The waves rise abnormally high and bite deep into the lumen of the stomach, often giving the appearance of three or four segmented round balls. Later on when ectasia has occurred from the continued weakening of the musculature, the peristaltic contractions are intermittent, with long intervening periods of atony, the contents lying dormant in the basinlike low stomach. When strongly stimulated by abdominal massage the stomach will suddenly stiffen up and be thrown into a violent convulsive standing contraction which may last but a moment and then suddenly relax into the previous ectatic atonicity.

Spastic manifestation.—The visualization of the inherent characteristics of the gastric musculature to undergo spastic or standing contractions when subjected to irritations from within, or reflexly from without, only became apparent when the röntgen ray was first used in examinations of diseases of the alimentary tract. The finding of a spastic contraction is of great value and cannot be disputed even by those who base their information on direct findings alone, for a spastic contraction will often denote the presence of ulcer in the ab-

sence of any other evidence. All parts of the digestive tract are subjected to spasm, the stomach, however, is the ground where manifestations of insult from within or from distal abdominal viscera most frequently make themselves felt.

Spasm in gastric ulcer may assume the following forms, dependent upon location and general characteristics: 1, The incisura or spastic hourglass; 2, diffuse or general gastrospasm; 3, spasm of the pylorus.

1. The incisura is due to a contraction of the circular muscle fibres occurring in the plane of the ulcer. It is manifested by a narrow, smooth, and regular indentation of the greater curvature. It varies in depth and width, depending upon the size of the ulcer. They are usually seen in the pars media in the vertical portion of the stomach, but may occur anywhere. When deep enough it may bisect the stomach into two sacs giving the appearance of the hourglass stomach. The two sacs are connected by a very narrow canal often assuming the shape of the letter B. The incisura is a persistent standing contraction, especially when the ulcer is in the florid stage. It does not disappear under active belladonna administration. While the incisura is not a constant accompaniment of gastric ulcer it may, however, at times be the only evidence of ulcer. An incisura may likewise manifest itself from reflex causes when diseased conditions exist in other abdominal viscera. It can, however, be differentiated by its transient nature, by its inconsistency in position, and by its disappearance under active belladonna administration.

2. Diffuse gastrospasm is a frequent accompaniment of gastric ulcer. It may be remote from the seat of an ulcer, differing from the incisura, and involves the most active portion of the stomach, the pyloric segment as far as the incisura angularis. It causes considerable distortion of the pars pylorica, often simulating carcinoma. The contour may appear angular or choppy or may simulate a corkscrew. Fig. 3 gives a fair indication of its appearance. The rhythmic peristaltic waves fail to pass over and very often the röntgenologist encounters great difficulty in the differentiation from malignant infiltrations. Only good doses of belladonna and the clinical picture will solve this problem. The spasm will interfere with gastric motility.

3. Spasm of the pyloric sphincter arises from irritation of an ulcer situated in the pyloric segment at or close to the sphincter. The pylorospasm may be so intense as to cause marked interference with the emptying time and the six hour examination will reveal a large residue, the stomach often not emptying until the next day. How the mechanism of retention is brought about and how the state of the pyloric sphincter governs the exit of the food under abnormal conditions will be discussed below.

Motility.—Disturbances in motility as manifested by retention at the end of six hours is present in about fifty-five per cent. of gastric ulcers. The closer the ulcer to the pyloric sphincter the greater will be the six hour residue. Ulcers situated in the pars media may not be accompanied by retention. If so, the retention is small and is situated to the left of the median line. In pyloric ulcers

the residue is large, crescentic in outline, and is centrally located, the retention, lying closest to the seat of the ulcer. The size of the residue varies from one quarter to three quarters or more of the meal partaken. Large retentions are also met with when the ulcer is in the active stage and is associated with an inflammatory exudate. These often simulate organic stenosis. When the active stage subsides the six hour retention becomes considerably lessened or may totally disappear. In ulcers situated at the pyloric sphincter the stenosis may be complete, and the meal may then be retained for several days, the ectatic stomach finally relieving itself by vomiting large quantities of food. The characteristic three layers of vomitus in gastrectasia are then observed. The incidence of gastric retention is not always due to the mechanical factor of stenosis, for retentions are continually encountered when the ulcer is situated remotely from the sphincter. Retentions may likewise arise from distant lesions of abdominal organs, such as appendicitis, cholecystitis, and renal calculi. Such retentions are due to disturbances in function of the pyloric sphincter, disturbances which arise from disordered vagus innervation manifesting itself in hyperacidity and hypersecretion. The pylorus becomes irritable and spastic and gives rise to the condition spoken of as pylorospasm. When lesions exist in a hypertonic or orthotonic stomach the retention due to pylorospasm will be greater than hypotonic lesions due to greater muscular strength. Under the fluoroscope the pylorus is seen to take on a sheared off or notched appearance. The meal is at first delayed in its passage and later on is seen to pass through in a very narrow stream, never filling the duodenum completely. Such spasm usually indicates ulcer at or near the pylorus. In

FIG. 3.—Penetrating gastric ulcer. Note the intense accompanying spasm in the pyloric region simulating a canalization of carcinoma defect.

ulcers situated distally from the pylorus the reflex spasm is only present in the first hours of digestion when food still fills the pars media. Later on, however, when the local irritation has disappeared the reflex pylorospasm will let up and the stomach will empty on time.

Ulcer situated at the cardia is a rare occurrence. It cannot be visualized on direct examination. The diagnosis must rest on the presence of indirect signs of cardiospasm, the lower end of the esophagus remaining filled and assuming a sausageshaped appearance, the food only occasionally dropping through in a thin stream. An incisura high up at the cardia may also be present. While cardiospasm may be the result of other conditions, a careful clinical history will aid in the diagnosis.

The röntgen methods of diagnosis of duodenal ulcer, like those of gastric ulcer, consist of: 1. Direct signs—visualization of the duodenal defect. 2. Indirect signs—hypertonus, hyperperistalsis, hypermotility, hypersecretion, spastic manifestations, and tender points.

DIRECT SIGNS.

Before entering into a description of the duodenal defect it would not be amiss to mention briefly the röntgen anatomy of the duodenum. The duodenum is made up of four portions: First, pars ascendens superioris, also called duodenal bulb or cap; second, pars descendens; third, pars horizontalis,

gular shape, as is seen in the fishhook or the other forms.

Duodenal defect consists of a distortion in the contour of the duodenum. The irregularity may assume any form or size, and may be seen on any of the borders, most often on the mesial border. The duodenal defect is due to organic structural changes in the walls of the duodenum. It may also be due to associated spasm. Carman states that the defect always appears larger under the röntgen examination than when seen at the operation, which he explains is due to the associated spasm. Figs. 4, 5, 6 and 7 give a fair idea of the different types of duodenal defects. They usually appear as craters which may be very small, Fig. 7, or sufficiently large to distort the entire surface of the duodenum, as is seen in the large clover leaf defect in Figs. 4 and 6. Sometimes the defect may appear as a niche, similar to gastric ulcer, and occasionally an accessory pocket is encountered. An incisura occurring in the plane of an ulcer is often seen. At times no defect may be visible but the duodenum appears small and contracted. When such obser-

FIG. 4

FIG. 5

FIG. 6

FIGS. 4, 5, 6.—Various types of duodenal ulcers showing the defect of the first portion of the duodenum. Note the persistent defect in the multigraph exposure.

and fourth, pars ascendens inferioris. The first portion or duodenal cap is the one of most interest to the röntgenologist. Nine tenths of all duodenal ulcers occur in the first portion. The duodenal bulb varies in size and somewhat in shape with the type of stomach. Rising above the pylorus, the duodenum communicates directly with the sphincter. The cap is one inch to an inch and a half in size and is triangular in outline, with the base below and the apex above. It presents a smooth and regular appearance. The duodenohepatic ligament anchors the summit of the first portion of the duodenum. In the subtonic type of stomach the duodenum is larger in size and is seen filled most of the time. This is due to the low and sagging lower pole of the subtonic stomach, which causes traction in the duodenohepatic ligament, thus increasing the bend between the first and second portions. In the steerhorn stomach it is often with difficulty visualized, appearing small and situated posteriorly to the pylorus, and may also be directed downward. It does not assume the typical trian-

gular shape, as is continually noted the röntgenologist should be on his guard, for there may be a small mucous ulcer present. Distortion in contour may sometimes occur from adhesions arising from the gallbladder. Such defects, however, do not present the regularity or constancy of an ulcer. Pressure on the outer border of the duodenum from an enlarged gallbladder does not offer any difficulty or differentiation. Finally a sufficient number of exposures must be taken to satisfy the observer as to the presence of a normal or abnormal duodenum. All positions should be utilized, including the first and second oblique.

INDIRECT SIGNS.

Hypertonus.—In duodenal ulcers the stomach assumes the hypertonic form. The alteration in type is due to the increase in tonus which may either be due to reflex stimulation arising from the irritable ulcer or from the more energetic contractions in the effort to overcome a spastic duodenum. Thus we often see a stomach of the fishhook type with a vertical axis change in position and form. The

stomach rises higher in the abdomen and assumes an oblique to a transverse axis. These changes in form and axis are due to the increased state of tonicity of the vestibular portion of the stomach. In long standing callous ulcers of the duodenum with stenosis the stomach will gradually assume

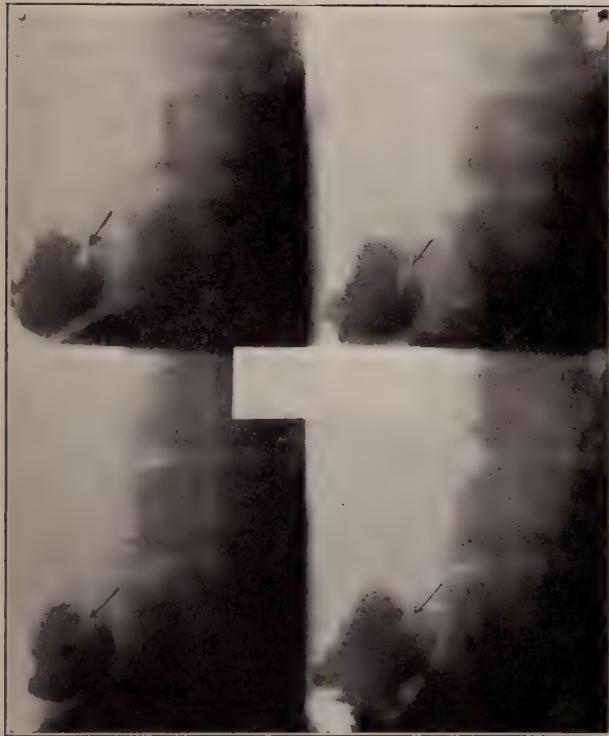

FIG. 7.—Defect under röntgen examination due to associated spasm. The surface of the duodenum is distorted.

the hypotonic and atonic forms from exhaustion of the muscular fibres, spoken of then as loss of compensation.

Hyperperistalsis.—Hyperperistalsis is characteristic of duodenal ulcer and occurs in a large percentage of cases. There occurs not only an increase in the wave depth but also in their number. The wave begins high up at the cardia on both curvatures. Several waves simultaneously travel briskly toward the pylorus. The four to five cycle stomach is most often seen. When a meal is given it is retained somewhat longer in the cardia on account of the increased peristole. When reaching the caudal portion the initial peristaltic wave is more intense and the meal is at once seen to pour out copiously through the duodenum. The normal five to ten minutes period of delay is shortened and the regular waves soon set in. The energy and depth of the waves are marked not only in the antrum pylori but high up in the pars media, the antrum however exhibiting several large deep indentations. As digestion progresses short periods of rest are noted, the stomach becoming completely relaxed and no peristaltic waves being seen. If gentle abdominal massage is used the stomach will at once stiffen up and again repeat the violent convulsive contractions. These periods of intermission increase with the size and extent of the ulcer and are due to an increasing exhaustion of the gas-

tric musculature in the effort to compensate the obstruction. With moderate degrees of obstruction the antrum appears distended and is a significant finding in duodenal ulcer. When the ulceration has extended to the pyloric sphincter the picture of the ectatic stomach of the pyloric ulcer with stenosis will repeat itself.

Hypermotility.—Hypermotility is another factor in duodenal ulcer, provided marked obstruction does not exist. As mentioned before, rapid evacuation is continually observed during the fluoroscopic examination, the meal passing with great rapidity through the duodenum often never allowing the duodenum to fill completely. The advance of the meal through the intestinal canal is also rapid. Normally the head of the contrast meal is seen at the hepatic flexure at the end of six hours, being evenly distributed in the terminal ileum, cecum and ascending colon. In duodenal ulcer, however, the advance of the meal is more rapid and the head of the advancing column is beyond the midportion of the transverse colon and may be seen as far as the sigmoid (Fig. 8), very little remaining in the terminal ileum. The stomach empties early. In uncomplicated duodenal ulcers it may empty within two or two and a half hours or even earlier. When hyperacidity, hypertonus, and associated pylorospasm supervene a small six hour retention is

FIG. 8.—Callous ulcer of the duodenum on the indirect evidence. Retention and colonic hypermotility at the end of six hours. Incidentally the ulcer defect of the duodenum is also seen.

met with. This retention is made up mostly of gastric secretion holding little of the contrast substance in suspension. If a tube is introduced no food particles are withdrawn but a large quantity of clear secretion with a little barium are obtained. Later, however, when stenosis takes place the six

hour residue will vary with the degree of the stenosis and will simulate pyloric ulcer. In such cases, aside from the duodenal defect, the presence of exaggerated peristalsis will always help in the differentiation of the two conditions.

Hypersecretion.—Hypersecretion is the fourth and final "hyper" characteristic of duodenal ulcer. It should be looked for only in the fasting stomach or at the six hour examination when using the

FIG. 9.—Note the intense spasm on the pars pylorica, both on the lesser and greater curvatures accompanying duodenal ulcer.

double Haudeck meal and can then be demonstrated by the presence of the horizontal base line of the *magen-blase*, and fluoroscopically by the visual succussion of the fluid. If the meal is administered in the presence of secretion it does not hug the lesser curvature but is seen to drop through the fluid like molasses through water. When the stomach is full with the buttermilk barium mixture, if secretions are present they will rise to the top and form a layer of a lesser grayish density intervening between the *magen-blase* and the meal. This is not due to sedimentation of the meal, for it becomes at once apparent, and furthermore the buttermilk mixture does not settle.

Spastic manifestations.—Gastrospasm is usually an accompanying factor in duodenal ulcer. It may occur in the form of an incisura or less commonly as a diffuse gastrospasm. Fig. 9 represents a constant defect in the pyloric segment due to reflex gastrospasm from duodenal ulcer simulating malignant infiltration. A reexamination after active belladonna administration relaxed the spasm and the distortion in contour disappeared.

Tender Points.—Tender points in duodenal ulcer are not a dependable sign. The writer has seen

many outspoken duodenal ulcers without tender points. When the ulcer is large enough, however, or is in the acute stage, or when periduodenitis is present, then tenderness is quite manifest. Similarly, in gastric ulcer the niche along the lesser curvature is invariably tender and is always due to the accompanying perigastritis.

The indirect signs of hypertonus, hyperperistalsis, hypermotility and hypersecretion are spoken of as duodenal irritation and are not pathognomonic of duodenal ulcer. Pathological conditions in distant viscera are frequently manifested in reflex duodenal irritation. In the presence of a normal duodenal bulb one should hesitate to regard the case as one of duodenal ulcer. While a small ulcer may exist, under the circumstances it is not commonly seen, and a careful investigation of other possible lesions should be made. It is, of course, superfluous to state that such examinations should be routinely performed. The efforts of the examiner will then be amply rewarded.

THE BENZYL BENZOATE TREATMENT OF WHOOPING COUGH.

By T. E. McMURRAY, M. D.,
Wilkesburg, Pa.

Satisfactory and immediate results can be obtained in the treatment of whooping cough by the use of benzyl benzoate. The dose given was from five to thirty minims every four hours, depending upon results. In some cases decided improvement was noticed from the smaller dose, in other cases larger doses were employed. In almost every instance the treatment determined subsidence of the paroxysms.

The effect usually made itself felt within forty-eight hours and in one instance there was relief after the second dose. As a rule the relief is immediate and complete. Although it is necessarily somewhat difficult to estimate the efficacy of a remedy in such a capricious disease as whooping cough, I think I am entitled to conclude from my experience that it not only does in many cases afford immediate relief of severe spasms of coughing, but it also seems to lengthen the interval between attacks. As far as my experience goes, this treatment gives rise to no undesirable results. I gave twenty minims to a child twelve months of age with no evidence of gastric or any other disturbance.

553 TRENTON AVENUE.

DIAGNOSTIC CHARTS AS A GUIDE IN THE STUDY OF GASTROINTESTINAL CONDITIONS.

By I. O. PALEFSKI, M. D.,
New York.

The correct diagnosis of abdominal conditions necessarily requires observation based upon the results of extensive clinical and röntgenological examinations. From the cases studied by us within recent years, we observed that errors in diagnosis were most frequently the result of brief histories or hasty examinations. Another common cause was the overemphasizing of one procedure at the

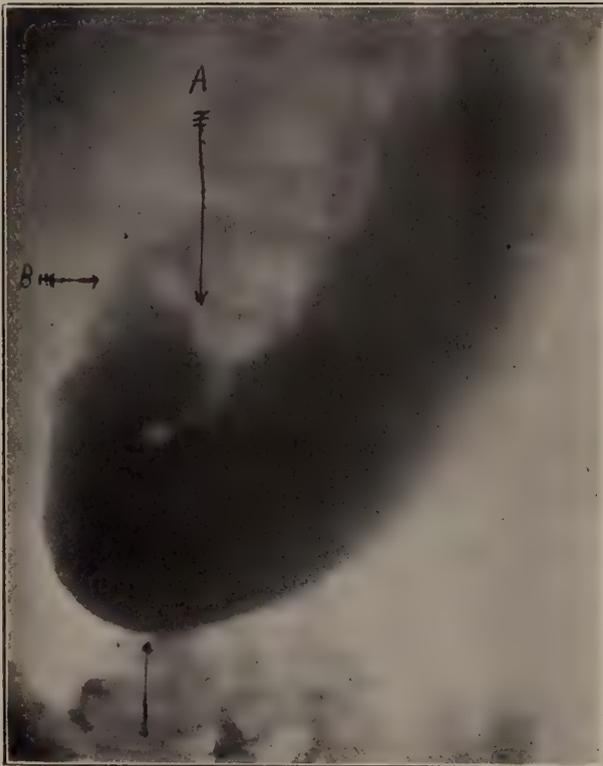

Fig. 1.—Filled stomach, erect posture; A, moderately dilated and drawn to right of spine; B, duodenum not properly filled.

expense of, or even to the exclusion of, other equally important ones.

Such studies must not only be made from every angle but the diagnostic data gathered must be properly recorded for reference. Gastrointestinal disturbances are sometimes the expression of an organic disease outside the gastrointestinal tract and which makes itself apparent months or years later. Hence all evidence must be noted and recorded. Again, the recording of such data must not entail too much clerical work as it is not practical in private practice. On the other hand, loosely kept records and prints of x ray negatives are likely to be misplaced and the record of the whole case soon becomes a matter of memory.

We have, therefore, devised a folding card system comprising four printed forms for the history, physical, clinical, and röntgenological findings. Prints of the reduced x ray negatives are attached and the whole can be conveniently kept in a record

Fig. 2.—Filled stomach, prone; normal appearance.

cabinet or bookcase. These charts require the least amount of writing as only abnormal or unusual findings need be recorded, while the unfilled parts represent the normal. A duplicate of this card is sent as a report to the physician.

The printed form for the history permits a de-

Fig. 3.—Six-hour plate; A, appendix well visualized.

tailed description of the personal habits, character of meals, menstrual and marital history, and a careful analysis of the symptoms of the present complaint. Improper habits, indiscretions in diet, gynecological disorders and previous pregnancies and labors, have a direct bearing upon the present

Fig. 4.—Forty-eight hour plate; A, appendix still visualized.

complaint in a large number of patients with gastrointestinal disturbances.

The printed form for the physical examination provides for a general examination and detailed description of the abdomen and fluoroscopy of the gastrointestinal tract. The findings elicited in the physical examination of the abdomen, are represented by their initials inserted at the corresponding areas in the diagram.

We believe that these folding charts¹ offer not only a convenient and timesaving method for the recording of data but will prove a guide to the busy practitioner in obtaining careful histories and physical examinations essential for correct diagnosis in abdominal conditions.

156 WEST EIGHTY-SIXTH STREET.

Resection of Double Kidney.—Frederick C. Herrick (*Surgery, Gynecology and Obstetrics*, June, 1920), presents his conclusions in the treatment of double kidney: 1. Resection of a diseased double kidney or the diseased portion of a single kidney may be advisable in order to save a necessary amount of kidney substance for the individual. 2. The resected end surface should be covered with fatty capsule. 3. There were found in the literature four other reported cases of resection of double kidneys.

¹The folding charts will be included in the author's reprints.

PLEURAL DISEASE IN INFANTS AND CHILDREN.*

With Special Reference to Empyema.

By HARRY LOWENBURG, A. M., M. D.,
Philadelphia,

Pediatricist to the Mount Sinai and Jewish Hospitals.

Dry pleurisy is common in infancy and childhood. It occurs as a primary disease but more often is secondary to lobar or bronchopneumonia, forming a part of the complete clinical picture of nearly every case of the first. Nonpurulent pleural effusion is more often a primary disease than dry pleurisy. It, too, more often follows lobar pneumonia. Purulent pleuritic empyema commonly follows pneumonia and may rarely be a primary disease, or rather it occurs as a sequence to or is a secondary stage of primary nonpurulent effusion. In infants and young children tuberculosis as an etiological factor plays comparatively a minor rôle.

DIAGNOSIS.

Years ago I drew attention to the fact that on the left side in infants and children the breath sounds are harsher and louder than they are on the right side. This fact is too little recognized and leads to the suspicion of fluid on the right side when no fluid exists. It must further be borne in mind that the breath sounds, especially in infants but also in young children, are sometimes not at all interfered with as to their transmissibility and in the majority of cases but little. This is due to many causes—the thinness of the chest wall and frequently because there is either a compressed (carnified) or consolidated lung from which bronchial breathing emanates. This, being loud, is more readily transmitted. Hence reliance for a conclusive diagnosis may not be placed upon auscultatory phenomena.

Percussion yields the best results. Two percussion phenomena are of particular value, as follows: 1. There is a widespread area of impaired resonance or dullness (depending on the amount of effusion) which is out of proportion to the degree of dyspnea. In other words, if the same area of impairment depended upon solid lung there should and would be very difficult breathing, perhaps orthopnea and cyanosis. Impairment in the axillary spaces or the lateral aspect of the chest is always highly suggestive. 2. Just as important is the widespread area of a sense of increased resistance which is revealed by what may be termed light massive percussion or, perhaps better, light palpatory percussion. This is practised by lightly tapping the thorax with the tips of five fingers of the outspread hand. The difference experienced between the two sides in on-sided effusion is extremely well marked. With these two signs in evidence the results of thoracic puncture, the concluding evidence of fluid, if positive, but not of the absence of fluid, if negative, may be predicted with almost absolute surety.

A word as to which interspace should be the one of preference for thoracic puncture may not be amiss. On this topic textbooks should be rewritten. No special interspace may be named. Puncture

*Read before the Northern Medical Society, as part of a symposium on pleural disease, January 23, 1920.

should be made where physical signs indicate the presence of fluid. Space for discussing the value of x ray studies, which should always be made in hospital cases, if for no other reason than for purely pedagogical purposes, is not available, and for the same reason discussion of the treatment of nonpurulent pleural effusion will be omitted.

When asked to participate in this symposium I eagerly accepted mainly for two reasons. First, it gave me a formal opportunity to say something frankly, and I trust without offense, to the surgeons; second, it gave opportunity to express, with due humility, in the capacity of pediatric internist, certain views as to the surgical treatment of this serious and death dealing condition. These views, in my judgment, in principle at least, offer encouragement as to the possibility of a greater number of cures. I desire it to be borne in mind that the opinions here expressed are personal ones, given, however, as a pediatricist and are born of the disastrous results experienced in many cases, handled by competent surgeons. If any of my hearers desire to apply these views to the adult they do so on their own responsibility.

CRITICISMS OF SURGERY AND OF SURGEONS.

The surgeon has taken from the medical man, one by one, his right to treat disease after disease, and perhaps justly so. His conquests, however, have made him arrogant (shall we say egotistical?) and even at times insolent and abusive toward his medical colleague, who conscientiously, and not always wrongly, may differ from him. Appendicitis, gallbladder and pancreatic disease, malignancy in its protean manifestations, hernia, gastric and duodenal ulcer, pyloric obstruction, goitre, uterine fibrosis, tonsillar disease, prostatic hypertrophy, etc., have rightly been removed from the realm of the medical idler, the therapeutic procrastinator, and have been preempted by the surgeon. Woe to that medical philosopher who presumes to take sides against his surgical brother in dealing with the conditions aforementioned! How scathing his chastisement! How humiliating his ridicule! How damning his censure! But unlike Duncan, the illustrious king of Scots in Shakespeare's *Macbeth*, he, the surgeon, hath not borne his great office so meekly. To misquote further the bard of Avon, he assumes a virtue and he has it not, with reference to this disease, empyema. He has taken this disease to his bosom as his own. Like the ubiquitous traffic officer automatically he raises his warning hand and says "Thou shalt not. This is the acreage for angels' feet to tread and fools may not enter. You have no opinion worthy our contemplation or consideration. Do not forget ye are but medical men and in matters surgical ye dare not speak. Content ye therefore yourselves with making mistakes in diagnosis and with telling us where pus lies concealed after we resect the wrong rib and we will do the rest. And verily so it comes to pass. The rest is done and often it is for long and frequently it is a rest eternal and everlasting!"

To face facts, may one not ask what in all honesty has the surgeon done for empyema? Do his results warrant his right to assume dictatorship over

this disease or to refuse the advice and counsel of his medical colleague? Has he provided us with a clear cut reliable method of procedure based upon old well tried principles or enunciated upon a new but demonstrable hypothesis? In my experience he has done neither. He can approach no single case with a reasonable degree of definiteness that this will follow that. His results fall all but short of being a reproach to himself and his profession. The salvation of both lies in the fact that there is probably a limit to human effort. But the surgeon fails to recognize that this applies to himself and to surgery but (shall we say generously?) grants this distinction to his medical coworker. The fact remains, however, that both the surgeon and surgery have failed to solve this problem. The former has been myopic in his viewpoint. He has not made the best use of the means at hand. He has limited the application of simple principles which are limitless in their scope. Hence the total morbidity and total mortality of empyema remain unchanged. Hence the surgeon is helpless in so far as he is forced to seek information and to accept advice in spite of himself irrespective of its source, be this even from, in his judgment, the mind of the avirile medical man.

ADVICE TO THE SURGEON—INCLUDING THE EXPRESSION OF THE VIEWS OF A PEDIATRIC INTERNIST AS TO SOME OF THE PRINCIPLES UNDERLYING THE SURGICAL TREATMENT OF EMPYEMA.

The pediatricist has no quarrel with the surgeon as to the necessity for the surgical treatment of empyema. Neither has he nor has any sane physician any quarrel with anyone who advocates thorough drainage as the *conditio sine qua non* in the treatment of this disease. Anyone who, however, has witnessed the poor and uncertain results already referred to which commonly follow costatectomy, which are served up to the medical man and his patient with a monotony worthy of the effrontery and calm stoicism of the proverbial boarding house mistress, as the piece *de resistance* of the meal, must seriously differ from the surgeon as to how best drainage is to be induced.

Costatectomy, in my experience at least, is responsible for no more recoveries than is simple, well conducted, and intelligently performed thoracotomy. In truth, it has not given as good results, for I have witnessed more recoveries and prompter ones from this procedure than from costatectomy. Hence it is my conviction that costatectomy never saved a case of empyema that would not have been saved by thoracotomy. Surgeons are to blame for this. They do not conduct the aftertreatment in their cases with the patience and care which are required, and it is but a few days after the costatectomy is performed that the same conditions obtain which call forth and warrant the surgeon's criticism of the average thoracotomy, viz., a walled off sinus of the chest, leading to where no one knows, and probably draining anything but the proper area. It is no argument in favor of costatectomy to say that a larger opening may be made than by thoracotomy. This larger opening is of no

avail if it does not drain the proper area, and this often happens, because most good surgeons are poor diagnosticians. Better a small opening made by a thoracotomy over the area to be drained than a larger one made by costatectomy over a dry area. However, the truth about the proper treatment of empyema will never be reached by arguing the respective merits and demerits of these two surgical procedures. Both may give good results if properly performed, and both may give poor results if improperly conducted. What is needed first is a proper diagnosis of the exact location of the pus. After this the crux of the situation lies in securing the greatest amount of thorough drainage and disinfection with the minimum amount of trauma. If a thoracotomy will do it, that is the procedure of choice; if not, a costatectomy must be performed. Here is where good judgment is necessary. In my experience, simple, well conducted thoracotomy done in a manner to be described will give the best results.

WHEN TO OPERATE.

No empyema should be operated upon as soon as diagnosis is made, unless the mechanical disturbance resulting from the effusion itself is so great as to cause alarming symptoms; at least, no radical step should be undertaken. Simple aspiration may be done at first, purely as a measure of relief. The reasons for this are plain. No opening in the chest may be made and maintained without the development, at least subsequently, of pneumothorax. Clinically it has been experienced that pneumothorax, within certain limits, is a bugaboo of the past and may be ignored, inasmuch as its influence is negligible as far as retardation of recovery is concerned. Nevertheless the work of Major E. A. Graham and Captain Richard D. Bell clearly indicates the lethal influence of pneumothorax, due to a large opening in the chest wall, in cases where the entrance of air into the lung is impeded by obliteration of the alveoli or bronchi, i. e., where the pressure of the air entering the thorax through the artificial opening exceeds that which enters through the normal channels. Asphyxia promptly supervenes. These conditions obtain in nearly every case of empyema, inasmuch as acute pneumonia precedes or accompanies the disease. Hence at this stage the danger from acute pneumothorax is real and readily apparent. Later, after the pneumonia has subsided, the influence of the pneumothorax within certain limits, as that induced by the average thoracotomy or costatectomy, may be ignored.

Further, patients in whom the temperature remains high are poor operative risks and frequently become extremely septic and succumb to this condition. Those in which the temperature has struck a lower level or even becomes normal, and those in which the effusion is in fact not only purulent but thick, give the best prognosis. Cases in which the fluid is "on the turn" often do badly. The former may be said to be ripe. Hence cases in which the diagnosis is made late or when the diagnosis was missed do best of all. To summarize, therefore, it may be said that no empyema should be operated upon until the evidences of acute pneumonia and

of hyperpyrexia have disappeared and until the pus has become thick.

The following method of handling empyema cases is followed in my private work and in that portion of the pediatric service under my control at the Mt. Sinai Hospital:

The diagnosis is made by physical signs. It is confirmed by exploratory puncture over the area as indicated by these signs. The pus is studied physically (most important) and bacteriologically. An x ray examination of the chest is made and carefully studied with the röntgenologist for evidences of lung consolidation. If this is present and the fever is high nothing is done, or aspiration is practised if indicated. When these have disappeared an ordinary curved or straight adult sized trocar and cannula, such as that used to do paracentesis abdominis, is pushed between the ribs, where a careful study of the physical signs and of the x ray plate and the results of puncture indicate the best situation for drainage, and as much pus as will is permitted to flow into a pus basin, the entrance of air being ignored. The cavity is gently washed with a warm Dakin's solution, the volume entering the chest at one time, never being permitted to equal or to exceed the amount of pus removed, otherwise excessive coughing ensues. A rubber tube large enough to fit the opening is fixed in place, and through this once or twice a day the cavity is irrigated. I have treated many cases this way, having the patients brought to the office. When the temperature subsides the washings are gradually discontinued, and finally the tube is removed and recovery ensues. The success of this method depends upon the proper placing of the drainage tube so that it drains the bottom of the cavity, and it must be carefully considered which is the bottom, when the child is sitting or reclining. Hence it is important to indicate which position is the best for the patient.

If the temperature rises again careful physical and, if necessary, an x ray examination is again made, and if the needle reveals pus this area is treated in exactly the same manner. It may be well to make x ray studies with the tubes in position to see that they are properly placed. Fenestrated tubes are employed. If more than one tube is in the chest at one time it is desirable to secure through and through drainage, in other words, to see the fluid leave the thoracic cavity by one or more tubes, inserted at various places between the ribs, after the fluid has been gently injected through any one of them. This would indicate that communication is established between the areas drained and that adhesive bands are few.

To summarize again, it may be said that our studies lead us to believe that multiple thoracotomy, or, if you will, multiple costatectomy, to satisfy the obsession of the "costatectomatized" surgeon, done at different levels of the chest wall or over the areas where it is positively revealed that pus exists and that these areas are not drained by the original opening, will be the primary operation of choice, even in cases of empyema where it is known that a large free effusion exists. Thus with two or three or more tubes inserted between various ribs, some just within the cavity and some placed deeper

as the x ray may reveal the necessity therefor, every hour, or every two hours, or every three hours, or more, thorough irrigation of the entire cavity may be done with warm Dakin's solution with scarcely any disturbance to the patient. When discharge ceases and when the culture reports become negative irrigation may be discontinued and the tubes removed. This method is thought to be decidedly more practical and thorough and scientific than that advocated by a prominent surgeon who does a large single thoracotomy and places a series of tubes in the thoracic cavity in a hit or miss fashion, i. e., admittedly he does not know exactly what direction they will take but hopes they will drain the areas affected. Through these tubes he practises frequent irrigation.

The advantage of the method proposed over this is that in encysted cases the definite diseased area is drained, and where free fluid exists the danger of encystment is lessened, since the whole cavity is irrigated and drained thoroughly because the fluid enters and leaves at various levels, from the lowest to the highest, and drainage takes place whether the patient is either prone or erect.

CONCLUSIONS.

1. Surgeons and surgery have failed to give a definite method for the treatment of empyema.
2. Their right to preempt this disease is therefore denied.
3. A correct diagnosis as to the location of pus must precede all methods of treatment.
4. No patient should be operated upon until the evidences of pneumonia have passed and until the temperature has subsided and the pus has become thick.
5. Aspiration should precede permanent drainage, if there is mechanical interference with breathing, until the conditions mentioned above have been met.
6. Neither thoracotomy nor costatectomy *per se* offer any special advantage to the patient if indifferently performed.
7. The size of the opening is not nearly so important as the position of the opening.
8. Thorough drainage with proper irrigation of the infected area or areas, with a minimum amount of trauma, is desirable.
9. For this reason alone thoracotomy is to be preferred to costatectomy.
10. Personal experience would seem to indicate that multiple thoracotomy is the operation of choice.
11. A reasonable amount of pneumothorax in the absence of pneumonia is negligible.

2011 CHESTNUT STREET.

The Nutritive Value of Commercial Corn Gluten Meal.—Carl O. Johns, A. J. Finks, and Mabel S. Paul (*Journal of Biological Chemistry*, March, 1920) found that eighteen per cent. of whole, ground, yellow corn meal furnished an adequate supply of water soluble vitamins to rats. Commercial corn gluten meal supplemented by dried brewer's yeast, whole, ground, yellow corn, or cocoanut-press cake furnished the necessary protein for normal growth.

TREATMENT OF TUBERCULOSIS.

Clinical Case Reports.

BY BENJAMIN S. PASCHALL, M. D.,
New York.

(Concluded from page 98)

CASE VII.—D. K. is a patient of whom I was particularly proud for a long time. He made a wonderful record for himself and was apparently well at the end of his twentieth dose. He was a young man twenty-five years of age with both kidneys infected and numerous definite pulmonary lesions. There appeared to be considerable activity in the lungs though tubercle bacilli were not demonstrated in the sputum. They were repeatedly found in the urine. After the twentieth dose he concluded to stop. We warned him emphatically that the disease would return unless he was treated to the point of three negative reactions, but we did not know till afterwards that he had taken up Christian Science. He discontinued treatment in 1916. For three years he did very well and then the disease began to return. The last year has been a bad one for him but he is still sticking valiantly to his cult.

CASE VIII.—L. E. E. is interesting because he had genitourinary tuberculosis in addition to acute nephritis. He was a marine engineer aged forty, and had numerous sinuses from old tuberculous abscesses, all of which promptly healed on mycoleum. He was treated in an extremely irregular way because of his occupation but we seemed to keep him alive year after year by giving him an occasional dose. He had tubercle bacilli in his urine and albumin. These finally disappeared and his albumin dropped from four per cent. to five per cent. to a trace when last seen. I put him on treatment in 1911 and saw him last in 1917. A case of this kind is interesting because it illustrates the effect of mycoleum over long periods of time in the most hopeless kind of a patient who is in too bad condition to work and who still manages somehow to hang on to his position. There is nothing to be done to improve the hygienic conditions and the patient himself is and has been for years a wreck and a derelict, just holding on to life by a thread.

Of one thing I am convinced and it is the thing I am trying to make clear in this paper. If we cannot cure many of these old, hopeless, long standing chronic cases, we can at least patch them up so that they can live along in comfort and support themselves and their families and feel well enough to enjoy life at the same time.

CASE IX.—O. O., aged twenty-two. He was long suffering, and had a long standing, tuberculin treated prostatitis and epididymitis. He was placed on treatment in 1915 and given fifteen doses of mycoleum. His symptoms disappeared, his prostate subsided as did his right epididymis. His left had previously supplicated, leaving a sinus which closed. His Wassermann was negative and he had never had gonorrhoea. During his treatment he did heavy work as machinist in railroad shops.

CASE X.—W. I., colored, aged thirty-six, ship's steward, was an interesting patient. He had genitourinary tuberculosis; the kidney, bladder and pros-

tate were involved. The Wassermann was negative but he probably had a latent gonorrhoea of long standing. After the sixth dose of mycoleum an enormous abscess developed in the lower hypogastric region, supposedly from a tubercle in the anterior bladder wall. He was taken to the hospital but the abscess broke before he reached there and there was nothing for the surgeon to do but make the observation that it was evidently tuberculous and that it had pointed both ways, since the urine was pouring freely through the torn bladder wall.

Accordingly, he sutured up the rent in the bladder wall in the forlorn hope that it might hold. Three weeks later the patient left the hospital with the area completely healed and in apparently excellent condition and when last heard from three years later had remained well. The surgeon then wanted to know if it was the rule that my cases of tuberculous abscesses healed without sinus formation and he was told that it was the invariable rule provided the patient had received six doses of mycoleum.

When one comes to tuberculosis of the bones and joints, a consideration of their pathological conditions becomes necessary. Here the disease invades two main structures and confines itself so exclusively to them that the surgeon takes constant advantage of the facts elaborated by the pathologist. Tuberculosis of the bones invades the synovial structures and the red lymphoid cellular spongy or cancellous portion of the marrow of the bone. If it invades the epiphyses first from the blood stream and then finds its way to the joints by extension, it is in its earlier stages easy to control, because it is the portion of bone which is most perfectly supplied with circulation and into which wax splitting ferments most thoroughly and quickly penetrate following mycoleum injections. If, however, it invades the synovial membranes and joint cavities primarily, as it frequently does in adults, the picture then becomes just the opposite.

Here we have about the worst structures in the body for exchange of fluids, and wax splitting ferments being of the peculiar physicochemical composition described it is easy to understand how they would penetrate into this particular area of disease with great difficulty until the disease had progressed to a stage where the synovial structures had become sufficiently disintegrated for the wax ferments once more to exert their characteristic action. This puzzled me for a number of years because my early cases with synovial affections did badly while the later ones began to clear up from the very first dose, in the majority of cases. Adult forms of bone and joint tuberculosis also recover less rapidly than they do in children no matter in what form the disease appears.

In tuberculosis of the bones and joints of children, the immunizer must realize that while the advice and help of the surgeon is invaluable, the necessity of administering from six to twelve doses of mycoleum is of paramount importance before any drastic surgical measures are thought of, after which they will be unnecessary. If this can be accomplished first, the surgeon, if he does anything at all, can proceed as if the involved bone or joint

were a sterile cavity. Necrotic material or sequestra may be removed and the rest may be safely left to take care of itself.

CASE XI.—H. S. was sent to me early in 1909 with a tuberculous knee of two years' standing. He was four years old. His mother and sister were tuberculous and received treatment. This is one of those cases which had been observed over a long period of time but not treated with mycoleum until late in the process. During the first five years, with plaster casts and other suitable orthopedic appliances, the knee was kept, as we thought, in fairly good condition. It was necessary to keep some sort of apparatus on most of the time to prevent undue contracture, but it was evident that the child was growing up without showing any tendency to throw off the disease constitutionally even with the best of treatment, which he certainly had. He was first treated with tuberculin, except three years when the family was in another city. In 1914 he returned and we started to give him mycoleum, but it immediately became apparent that its use had been postponed too long and that the necrosis in the knee joint was too extensive to be longer ignored, and accordingly he was turned over to the surgeon. As soon as they opened the knee, it was evident that the damage had become so great that it was doubtful if excision would be feasible, though it could be tried, with a subsequent amputation if this failed. We decided that he had not been treated thoroughly enough with mycoleum and also argued against excision, on the ground that even this could be done later. For this I was properly rebuked by the surgeons, but the boy's mother and I refused to be moved. There was a cavity where the knee joint properly belongs into which one could have inserted a small sized orange after it had been curetted. Eighteen months later I had an almost perfect functional result, a straight leg which could bend to a right angle, and less than one quarter inch of shortening, and the x ray showed complete bone replacement. At the present time after six years it would be hard to convince anyone, even the most experienced, of what the boy has been through in the way of damage done, taking into consideration the causative factor of tubercle bacillus. The surgeons were my friends and they knew some very good things about mycoleum, but they could see no possible chance for the bone to fill in in the first place or the prevention of ankylosis in the second.

We did have to keep working to prevent the second complication, but we managed to get a fibrous covering that answers very well for a joint in the knee.

CASE XII.—Mrs. H. C. developed a tuberculous synovitis in the right hip which terminated in abscess formation. The pus was evacuated by simple incision and she was sent to me for treatment. She received twelve doses of mycoleum; the sinus promptly healed and she was discharged apparently cured. She has remained well since.

CASE XIII.—B. V. W. came from a country hospital, took her doses and returned from whence she came. She was aged twenty-seven and suffered from tuberculosis of the hip. She also had intes-

tinal tuberculosis. Both had been of many years standing and she had been a public charge for a long time. Somehow, she heard of me and the county authorities allowed me to treat her. After nine doses of mycoleum she was apparently well and returned to work for the first time in many years as maid in domestic service. I do not know whether or not she relapsed.

CASE XIV.—J. O. N., aged thirty, farmer, was operated on a number of times for tuberculosis of the elbow. It had involved the joint and there was considerable ankylosis when I first saw him. He was absolutely unable to use arm or hand and his pain was so great and so constant that he spent most of his time in the barn so that his wife and children could not hear him moaning in his suffering. When I first saw him, he could not hold an empty tumbler in the right hand and his surgeon sent him to me as a sort of a forlorn hope before doing an excision of the elbow. He received sixteen doses of mycoleum, made the usual recovery and since he lived where it was impossible to have the surgeon constantly limber up the stiffened arm, I suggested that he rig up an orthopedic appliance in the barn with the crank of the grindstone which would work free the elbow joint. I did not see him for several months after that but when I did I asked him about it. He said he had not used it because loading the team with two hundred pound milk cans twice a day had the same beneficial effect and driving a team of spirited horses tandem over rough roads twice a day had a straightening effect. His course of treatment extended over fourteen months. I might add that the pain stopped six hours after the first dose had been administered and never returned. He has remained well since that time.

What has been said before in regard to the important points in differential diagnosis particularly applies to intestinal tuberculosis. Gonorrhoea must be excluded in women. Typhoid fever sometimes simulates tuberculosis, but repeated attacks with suspicious pulmonary findings aid in making a provisional diagnosis. Usually the appendix has long since been removed by an earlier observer of one of these intestinal attacks. Care must be taken to differentiate the acute flare up with stenosis or obstruction plus the recurring attack. The gas, the exquisite tenderness, the constipation, the rigidity, the distention and the vomiting, sometimes fecal, together with the extremely severe paroxysms of pain, and often the fluid in the flanks, should immediately arouse suspicion of this form of tuberculosis, and when there is in addition a rapid pulse and moderate temperature the disease is usually well advanced with considerable accompanying peritonitis.

If one gives a dose of mycoleum to a patient in the midst of an attack of this character and a reaction follows (characterized by the occurrence of immediate soreness and swelling at the point of injection which continues to increase in size and soreness for several days together with constitutional symptoms accompanied by fever) one may then expect to see an immediate subsidence of the symptoms of the disease within a few hours and continuing to decrease in severity until they have disappeared entirely. The patient then goes about his

business and provided he takes his doses within reasonable limits of the prescribed intervals, there will be no further trouble and he will make a perfectly monotonous record for himself from this time on. There is nothing more dramatic than to see a bad case of this kind after the first dose.

CASE XV.—Mrs. S. E. B. was a patient of seventeen years' standing. She had been operated on and the peritoneum was seen to be studded with tubercles. She was sent home and continued to become worse in spite of good hygienic surroundings. Tuberculin was tried in competent hands without benefit. She was thirty-five years old and a confirmed invalid with a constantly elevated temperature and pulse. I put her on mycoleum in May, 1912, as a sort of last resort, in the hope that it might do her some good but that at least it would not do her any harm. She gave me one of those early surprises by getting up out of bed at the end of the first week and never going back to it. Please do not think that this is a miracle story until the rest is told. She also never ceased to tell about that first reaction and what it did to her leg. It is perfectly true that this is not an enjoyable form of treatment and no living human being would take it if were not for the overwhelming evidence to the sufferer of the subsequent benefit. She received fifteen doses during the succeeding three years, made a perfect recovery and has remained entirely well since that time.

Pulmonary tuberculosis deserves a separate consideration altogether from the forms hitherto discussed. The histology of the lung tissue must be kept constantly in mind when considering the feasibility of bringing wax substances and wax antibodies into intimate contact with the tissues, and the classification of the three main forms of pulmonary infection into fibrous, caseous, and general miliary does not materially alter the present description of sequences. Of course the fibrosis is the least permeable and the acute miliary form the most permeable to antibodies of this nature, while the caseous processes stand midway between.

Acute miliary is the most favorable form of pulmonary tuberculosis to treat, up to a certain sharply defined point, when the picture becomes reversed and the prognosis becomes absolutely unfavorable. This occurs as soon as the blood stream is sufficiently overloaded with toxins to disturb the antibody forming functions of the infected host, and in acute miliary forms it happens with great suddenness. Of course each case is usually more or less of a mixture of all three forms with one or the other predominating, but the encapsulating tendency is shown much earlier in the pulmonary than in other forms of tuberculosis, or else symptoms which make themselves known to the patient are prone to occur so much later in pulmonary forms that the therapeutic application of mycoleum becomes more difficult. There is a peculiarity of ferments of the lipase class before mentioned whereby they diffuse into infected areas with extreme slowness, which is an exceedingly important one, since the immediate action of the wax antibodies produced by an injection of mycoleum can only be successfully directed against those tubercle

bacilli which are actually free in the tissues or blood stream. Those organisms which are much more deeply seated and surrounded by the usual inflammatory area, including connective tissue, are only reached by degrees, and in some instances not until there has been an actual softening of the area in question. Since the number of free organisms at any time is small in comparison to those more or less deeply buried, it follows that the immediate reaction is always less than would be expected, while the length and ultimate degree of the reaction is of paramount importance. The reason for monthly intervals between doses is determined by these considerations. It is not uncommon in certain cases to observe a marked inflammatory local reaction keeping up for two and often three weeks after the injection has been given. In this report of pulmonary cases we will describe only those which present features of more than ordinary interest.

CASE XVI.—M. A., aged nine, pure American Indian, was brought to me with acute pulmonary tuberculosis. Both lungs were well dotted with tubercles of moderate size, and there was a running temperature of 104° in the afternoon and a pulse of 130 all the time. She had been treated with tuberculin for nine months without benefit. I put her on mycoleum in December, 1914, and gave her twelve doses in the following year. She made an apparently perfect recovery and was discharged with a normal temperature and pulse. Three months later she relapsed and the whole condition seemed as bad, even if not worse; her temperature was 104°, and sometimes as high as 105°, with an average pulse of 160. Of course her age was in her favor, but her race was against her, as none of these children from Alaska down to lower California have ever been reported to recover if pulmonary tuberculosis set in. Her sputum was swarming with tubercle bacilli and it was evident that she held her immunity badly. Accordingly I put her back on treatment and gave her twelve more doses during the second year. I did not dare to space the doses for fear of relapse, but at the end of this second course she seemed so well that I decided to space to ninety day intervals. Since that time she has received two doses a year until this year, when she was finally put off treatment. She is at the present writing normal and healthy in every way. There is absolutely and positively no doubt but that this patient would have died without mycoleum. She had been sick two years when I treated her, and was in very bad condition when first seen.

CASE XVII.—J. A. is another patient of the same type. He was thirty years of age and suffered from acute miliary tuberculosis. He was constantly being treated with a few doses, not enough to immunize him, but just enough to put him on his feet again when he relapsed, so that he could return to work. I first saw him in 1909 and treated him with tuberculin in addition to rest in bed in my sanitarium until his acute symptoms had subsided, but he did not improve much, as his case was of the acute type from the first. His exacerbations were always most severe with exceedingly high temperatures. He was an engineer and spent most

of his time going from place to place, unless he had to come in and be patched up. When he was out of work and out of money at the same time he would go without food for days.

These facts did not aid in the treatment, but it is necessary to mention them because every tuberculosis specialist knows how injurious these things are, and to show that mycoleum has not been used under conditions which were ideal but under such handicaps as physicians encounter in general practice among patients suffering from this disease. He had a bad relapse in 1913, received three doses, cleared up and went to work. There was another relapse in 1914, and both lungs showed scattered lesions over both sides to such an extent that I have him marked III on my records. During this time his temperature reached 105°, and once or twice went over this mark. During the next two years he received fifteen doses, and the disease apparently became arrested. He received five doses in 1916 and the lung findings cleared up. I saw him in 1918 and heard from him in 1920 when he seemed to be in good health. He weighed 135 when first seen in 1909, and weighs 155 at present.

CASE XVIII.—M. B. was seventeen when first seen. He had been raised in ideal home surroundings, and there developed a rather acute miliary tuberculosis about a year before he was sent to me. The x ray showed perihilar fibrocaceous tuberculosis somewhat bilateral, one side active and one side quiescent, which indicated considerable duration. He is marked II on the records. Temperature, 100°; pulse, 110. He was not under weight at the beginning but gained fifteen pounds on treatment and ten pounds subsequently. Received twenty-seven doses during 1914 and 1915, and has not shown the slightest tendency to relapse since that time. No change was made in his habits or mode of living. After the first six doses there was a complete disappearance of symptoms, which never reappeared. We did not get a final radiograph because the physical signs were perfectly satisfactory and he had to pass through other hands than mine. Tubercle bacilli were found in the sputum several times before I put him on treatment. This young man has been recently examined in the east and told that it is impossible to understand how he could have had a lesion from the present findings, although had a recent skiagraph been taken the old scars would have been quite apparent, since they are permanent. One must never forget to warn the patient if he has a second stage case that a subsequent examiner may be totally unable to make out a previous tuberculous infection treated with mycoleum unless this physical test is checked up by skiagraphic findings.

NOTE: Mycoleum is the name given to the preparation described in this article in the same way that tuberculin is applied to those proteid derivatives of the tubercle bacillus with which we are familiar. Mycoleum indicates a fatty or oily preparation from organisms of the genus mycobacteraceae, or the acid fasts, to which belong the tubercle bacillus leprosy bacillus and many saphrophytes widely distributed throughout the world.

THE WALDORF ASTORIA.

LONDON LETTER.

*(From our own correspondent.)**Problems of Parenthood.—Venereal Disease.—Clinics and Professional Secrecy.*

LONDON, May 22, 1920.

A second report of the National Birth Rate Commission has been issued recently in book form. The commission was instituted in October, 1913, by the British National Council of Public Morals, and its first report, which has been referred to in this correspondence, and in which the causes and effects of the declining birth rate were amply and frankly discussed, was published in 1916. The book had a wide circulation and was popular, in that, it was generally recognized that its contents were extremely valuable, and the demand was persistently made from numerous quarters that in view of the fact that the great war had exerted much influence upon vital problems of population, the commission should pursue its work. The commission was reconstituted, its members being drawn from various classes of the community. Among the many well known and eminent men and women who gave evidence before the commission may be mentioned the following: Professor A. Keith, Dr. Amand Routh, Dr. Mary Gordon, Inspector of Prisons, Mr. Sidney Webb, Mr. Bramwell Booth, Major Leonard Darwin, Sir A. Conan Doyle, Sir William Osler, Sir H. Bryan Donkin, Dr. C. W. Saleeby, Dr. C. B. Turner, Dr. Marie Stopes, Sir Rider Haggard, Professor Leonard Hill, and Mr. Harold Cox.

In the first place the commission discussed the fall in the birth rate during the war years, the reduction amounting, in 1918, to twenty-six per cent., in England and Wales. They estimate that in the period 1915-18 the loss of births attributable to the war was 543,000. In commenting upon voluntary restriction, which is denominated as one of the most important causes of the decline in the birth rate, the commission states: "At present the decline of the birth rate is greater where the quality of the children might be expected to be better. The childbearing is at present relatively the greatest among families and in homes in which the economic and social conditions do not allow of the healthy and proper upbringing of so many children. The reduction is taking place in the average size of the families, in always greater degrees in those classes where the condition for the welfare and education of the children are the best. This disproportion in relative birth rates is an ominous sign for the future of the nation and the Empire. The duty of parenthood needs to be urged upon the well-to-do, who can provide the more favorable conditions for the bringing up of a family. The commission points out that the responsibility of the country to parents in the discharge of their obligations must equally be asserted. If the community desires an adequate number of children of good quality, its members must be prepared to see that the burdens which weigh too heavily upon many parents are relieved. Among the reforms which have been proposed are: Proper housing, a living wage, training for and care of motherhood and infancy, facilities for edu-

cation, and relief from taxation proportionate to the responsibilities involved. The need for a properly regulated redistribution of the population of the sexes in the Empire may be mentioned as one of the most important methods of relieving the burden of parenthood in large families. Various schemes for the endowment of motherhood were considered, but having regard to the economic and other difficulties of the question, the commission did not recommend any of them for adoption.

As for the problem of illegitimacy, to which reference has been made in a previous letter, the commission found that, although the decline in legitimate births had alarmed the country, and the illegitimate child has come to be regarded as helping to make up for the deficiency of births in wedlock, there is no evidence that public opinion has, as a whole, undergone any fundamental change of attitude toward the unmarried mother, nor are there any signs of such a change coming about in the near future. Statistics for 1918 show that illegitimate births had increased by 11.6 per cent. while legitimate births have decreased by 1.6 per cent. As a result of these changes the proportion of illegitimate to total births, which fell to a minimum of 3.95 per cent. in 1901-05, has now risen to 6.26 per cent., the highest ratio reached during the past fifty years. The commission drew attention to the fact that by no means the least of the reasons for regarding the illegitimate child as a national problem are these: a, The number of illegitimates shows no sign of decreasing; b, the mortality among illegitimate is double that of legitimately born children; c, the nation cannot acquiesce in the destruction of children, legitimate or illegitimate. The neglect and ill nourishment of the unmarried mother and her child tend to increase prostitution, poverty, crime and disease and are a source of continual recruitment of the undesirable class by potentially worthy citizens. Summing up the national and international aspects of restriction the commission said: "Grave issues for the nation and the Empire are involved in the steady decline of the birth rate. In the event of a war similar to that just experienced, what would happen to us with a greatly reduced birth rate? As it is, the position is most disquieting, both here and there, for the indications are that in the homeland the population may not continue to increase, while in the Dominions oversea, without the aid of immigration, it will not, at the present rate, increase greatly, at least from additions of the British stock. All these enormous lands, with their countless native races, we hold with less than 60,000,000 white people, of whom 45,000,000 dwell in these little islands. But unless we add to our numbers how long shall we be able to fulfill our obligations in the face of recent developments of race ambitions? Extensive settlement upon the land would mitigate the evil, but modern men and women will not settle in numbers on the land. As our experience and that of Australia show, they prefer the city and the cinema. The commission pointed out that the outcome rested largely upon the women as having votes they now held the balance of power.

NEW YORK, SATURDAY, JULY 24, 1920.

OUR NEIGHBORS.

Bernard Shaw once made the remark that we should not be concerned about the bodily cleanliness of our neighbors. He said that we did not see their bodies, and went on to say, reasoning in the same fashion, that they should keep their faces clean. Popular wits often get to the heart of things, but just as frequently, by making the surface attractive, they keep away from the vital spots. So it may be well to stop and analyze and not be misled by our own silly laughter.

Epidemics have shown us that once disease is started in a lowly, filthy quarter it spreads like a prairie fire and sweeps everything before it. In most instances the mortality rates in epidemics are as high among the rich as among the poor; among the clean as among the dirty. We know that the majority of people do not realize the value of personal cleanliness and hygiene. The proportion of those ignorant in these matters in our own country is not as great as in many other countries. We must be interested in the cleanliness of our neighbors in order to protect ourselves. We must spread our knowledge so that the less informed may be better educated. As a matter of selfpreservation we have the right to enforce measures of sanitation among our neighbors.

With the advent of rapid means of communication, the airplane, fast ocean steamships, and the many links that are forged by international commerce and free-for-all wars, the inhabitants of the most remote quarters of the globe are brought to our

own firesides. These people have become our neighbors, though we may never see them. And so we have the right to guide the education and look after the health of the Senegalese, the Eskimo, the African natives; they are all our neighbors.

Health Commissioner Royal S. Copeland has returned from Europe with a report of the sanitary conditions there. He tells how travelers returning from a holy journey to Mecca filter through Persia and, passing up the Russian rivers, carry cholera to Russia and Poland; and how, through the Baltic ports the disease may eventually reach the rest of Europe and even America, unless we are watchful. He states that typhus is prevalent in Poland, Russia, Ukrainia, Lithuania, Rumania, and Hungary. Filtration plants have been destroyed, water supplies are contaminated, sewage systems are blocked. Plague is found in Egypt and adjoining countries.

It is not alone our duty to watch our ports to protect ourselves. Disease can not be combatted effectually in this way. We need only recall the influenza epidemic. There was not a remote nook in the entire world that was not reached by this disease. We should do everything in our power to clean up the dirty corners of the world. Through the bait of commerce we cleaned the Panama Canal. A good example. Why should we not extend this work to the more remote regions, for the people there are our neighbors. We owe it to ourselves, to protect ourselves. We shall not make this an issue of altruism and pretend we are doing our neighbors a good turn, even if this is true. The cleanliness of our neighbors is a vital affair to us, and the wit of Shaw will not help them in maintaining their privacy.

STERILITY IN THE FEMALE FROM GONORRHEAL INFECTION.

There are two types of sterility of uterine origin in the female, the septic form which is the most serious and frequent, and that due to a mechanical cause which is far less serious. The most important of the septic uterine sterilities is unquestionably gonorrhoeal infection, giving rise to metritis, usually of the corpus uteri. From here the process may follow an ascending extension, invading the tubes and periuterine cellular tissue. In some rare cases a virulent infection may result in rapid invasion of the uterine mucosa, adnexa, and peritoneum with rapidly occurring suppuration in all these structures. In cases where uterine and periuterine lesions exist simultaneously the explanation of sterility is

simple, but the same cannot be said when the infection is localized to the cervix. It is, however, certain that a gonorrheal cervical endometritis is one of the most frequent causes of sterility as is proved by proper treatment of this lesion, the woman becoming pregnant afterwards.

The puffing up of the cervical mucosa, the morbid changes undergone by the mucosa of the corpus uteri and purulent secretions prevent the spermatozoon from progressing upward. It is either arrested by a collection of secretions which forms a mucopurulent plug or is destroyed by the too great acidity of the discharge or the toxin it contains. It is probable that some importance must be attached to slight tubal reactions that are usually unrecognized. Clinically gonorrheal metritis is met with in three forms, viz., acute, subacute, and chronic, the latter being by far the most common cause of sterility. During the first year of married life the woman presents a leucorrhœa resisting all kinds of treatment, resulting from an old gonorrheal infection in the husband. The process in the wife develops quietly, without giving rise to any general reaction or pain. The discharge is free, composed of thick, sticky, yellow mucus. The body of the uterus is normal in size, the cervix enlarged, swollen at its middle portion and with an os surrounded by a red cuff formed by entropion of the cervical mucosa through which a large drop of pus will be seen exuding. But even when the corpus uteri is infected the lesions are always more pronounced in the cervix and becoming localized are difficult to overcome.

The gonococcus is not likely to show itself very much. Hidden in the folds of the mucosa, or lodged within it, the organism does not appear in the pathological secretions excepting at the advent of the menses. Completely sheltered in the recesses of the mucous membrane or in its glandular structures, the organism produces a progressive increase in the size of the cervix, an increase and occlusion of the glands, thickening on account of the development of sclerous periglandular bands and, when it comes forth from its lair, the result will be a reinoculation which clinically is made manifest by an unlooked-for relapse and a contamination of the husband, who tardily receives the results of his own work. Hence a vicious circle is established in which a marital gonorrheal infection passed on to the wife is, at the exit of the gonococcus, transferred to the husband.

Treatment is purely medical and above all should be mild. Nothing but prudent intracervical applications should be attempted. Under no pretext should a sound or curette be resorted to unless an experimental inoculation of the mucosa of the corpus uteri is desired. When the infection is of long standing

and the applications are insufficient, it will be necessary, in order to overcome the infection completely, to deal radically with the diseased structures by cauterization which is renewed every ten or twelve days. Usually, when properly done, from four to five treatments are enough. During the treatment the mucopurulent discharge will increase in intensity, but from one treatment to the next the diseased structures will be seen to become eliminated, the cervix gradually assuming its normal aspect and color, and pus no longer coming from the external os. Cure is usually complete if the patient does not receive a reinoculation and if, during the treatment, she remains recumbent the greater part of the time.

THE COLLOIDS IN GENERAL PRACTICE.

Colloidal therapy has progressed apace and a belief in its virtues appears to be based upon a sound foundation. However, it is well to remember that, although the use of colloids was introduced many years ago, colloidal therapy is really in its infancy. The average general practitioner as a matter of fact knows little concerning the colloids, and reading and hearing of successful treatment by this method of administering medicine is likely to be led astray. He is prone to believe that all colloidal preparations have an equal or similar therapeutic value, whereas this is far from the truth, and acted upon will produce very unsatisfactory results.

As pointed out in the *Prescriber*, June, 1920, the preparation of colloids is, in many instances, no very difficult matter; the difficulty begins in the attempt to make them therapeutically valuable. The general practitioner should satisfy himself that he is using colloids of the right strength, those whose therapeutic properties are sufficiently known, and those which are suitable for internal administration, orally or by intravenous injection as the case may be. Further, the colloidal preparation used must be stable, that is, "protected," for if it is not it is no longer colloidal and its therapeutic value vanishes. Also the preparation must be fresh, the colloidal state being obviously essentially unstable and subject to disintegration by certain substances existing in the atmosphere.

Provided that all these principles are complied with, it is argued by the advocates of colloidal therapy, that it is easily the most effective method of employing medicinal measures in the treatment of certain diseases. Colloidal mercury may be given wherever the employment of mercury is indicated; in this state it is only feebly toxic and is rapidly absorbed. The other colloidal preparations, according to many who have tested them clinically, possess merits of a like nature and in the case of collosol

manganese Mr. J. E. R. McDonagh, F. R. C. S., has recorded some remarkable results.

Perhaps it is too early as yet to attempt to place an estimate on the value of colloidal therapy. It will suffice to say that so far the results, on the whole, have been satisfactory and encourage the belief that there is a great future for this method of medication. It is necessary to state, however, that when employing colloidal therapy it is essential to use preparations which have been properly stabilized and are isotonic with the blood. Those which do not possess these characteristics are not only useless but may be dangerous.

LABOR, LUXURY AND THE SURGEON.

Most people would imagine that the condemnation of harmful luxuries by doctors would happen most frequently in the office with rich patients, but surgeons attached to large industries could tell that neither fines nor thought of others seems able to eradicate the love of finery. Three cases of finger or hand crushing have happened recently in laundries owing to rings being worn. The law decrees that all flatiron workers must be equipped with guards in front of the feed rolls to prevent the hands of feeders from being drawn into the rollers, and ringed fingers were found especially dangerous, yet nothing seems able to instill the idea of self preservation at the small cost of giving up some finery in work hours.

It is not only the girls but the men who sometimes put adornment before safety. Do they realize—just to give one instance—that the rim of a circular saw is moving at the rate of one to two miles a minute? Perhaps not, but the printed warnings against wearing rings or gloves are before their eyes. All the same, smashed fingers and hands appear with horrible frequency, and the public blame the employer for what was in reality contributory negligence on the part of the worker.

THE SEAPORT DOCTOR.

Psychology is preparing ever increasing tasks for doctors, not intentionally, but she is working with medicine concerning the permitted entry of aliens into America, says the *Journal of Applied Psychology*, March, 1920, proving that a sound industrial democracy must be built on racial psychology and putting the right man in the right place. We notice the French Canadians drifting to the cotton factories, copper mining, smelting and leather works; Croatians toward the mines, steel and kindred trades; Danes favoring leather and furniture factories; Armenians, cigarette making and peddling; Greeks liking blacksmithing, baking, shoemaking; Hebrews get into small manufactures of the sweat shop variety. The Chinese love to import; the French Swiss take to hotel and restaurant business, silk industries, embroideries, etc. There are also the big questions of nostalgia and the adaptability to

climatic conditions. Truly the life of the doctor in a seaport city will not be attractive until civic governments, local boards and employers understand the nature and cost of that which they demand in the way of careful judgment concerning incoming workers.

News Items.

Fund for Spanish Hospital.—The will of the late Mrs. Luisa de Navarro, of New York, leaves the greater portion of her estate to establish a hospital in New York for Spanish speaking peoples.

Medicine in Holland.—The Dutch medical correspondent of the *Presse médicale* comments on the unity of organization among Dutch physicians. Of 3,300 medical men in Holland, 3,200 are members of the Society of Medicine.

Northwestern University Buildings.—The schools of medicine, dentistry, commerce, and law of Northwestern University will be housed in new buildings which are to be erected at Chicago Avenue and Lake Shore Drive, Chicago.

Bequest to Bowdoin Medical School.—Dr. Addison S. Thayer, dean of Bowdoin Medical School, Brunswick, Me., announces that the late Dr. Frank Byron Brown, of Boston, of the class of '87, has bequeathed to the school \$1,000.

Police Hospital Fund Campaign.—A campaign for \$5,000,000 for a police hospital for New York City is under consideration by a committee interested in the project. The proposed hospital, which will have 300 beds, will probably be located in Brooklyn.

Dr. Carrel Honored.—An honorary degree was conferred on Dr. Alexis Carrel, of the Rockefeller Institute, by Brown University, at its recent commencement. He also received the honorary degree of doctor of science from Princeton University at the recent annual commencement.

Vacancies on the Staff of the Psychiatric Institute.—The New York State Civil Service Commission announces examinations to be held on July 31st to fill the following positions at the Psychiatric Institute, Ward's Island, New York, of which Dr. George H. Kirby is director; assistant in neuropathology, \$2,160; associate in bacteriology, \$2,360; associate in internal medicine and clinical pathology, \$2,360; senior physician, \$2,000. Applications must be received at the office of the commission on or before July 26th.

Health Commissioner Copeland Returns.—Dr. Royal S. Copeland, health commissioner of New York, has returned from a trip abroad to attend the International Housing Conference in London and the Royal Institute of Public Health Conference in Brussels. In a published interview following his arrival, Dr. Copeland gave it as his opinion that in the protection of the milk supply, food inspection, health supervision, infant welfare, school inspection, and protection of the public against disease, New York is superior to European cities, but that Europe has much to teach us in the matter of garbage disposal, and also that in Europe the question of housing is regarded from the viewpoint of a public utility.

Sonsonate Cleared of Yellow Fever.—The quarantine against the city of Sonsonate, in the southwestern part of San Salvador, has been lifted, and Dr. Bailey, of the Rockefeller Institute, has informed the Committee on Public Health that yellow fever has been eradicated there.

Smallpox in Glasgow.—Smallpox is still reported as being epidemic in Glasgow. The disease, however, does not appear to be spreading with any increase of rapidity, as the number of new cases remains about the same—four to six a day. Since its commencement the epidemic has been almost entirely confined to Glasgow.

Death of Professor Kretz.—Professor Kretz, one of the last living pupils of Kunderat, died recently in Vienna after a protracted illness. He was born in 1865, and after studying in Vienna, became the professor of pathological anatomy in Prague and later in Würzburg. His investigations were directed to the physiology and pathology of the liver, and dealt also with diphtheria and sero-therapeutics. His papers on antibodies and immunity, on disturbances of metabolism and the pancreas, as well as on embolism of the lung, are most instructive and afford a clear insight into the problems of these conditions.

Cambridge Honors Medical Men.—At the annual meeting of the British Medical Association at Cambridge, the honorary degree of LL.D. was conferred upon the following gentlemen: Sir Clifford Allbutt, regius professor of physic in the University and president of the British Medical Association; M. Jules Bordet, president of the Faculty of Medicine and director of the Pasteur Institute at Brussels; Dr. Simon Flexner, director of the Rockefeller Laboratories; Dr. Pietro Giacosa, professor of experimental pharmacology at the University of Turin; Sir George Makins, president of the Royal College of Surgeons of England; and Sir Norman Moore, president of the Royal College of Physicians of London.

Examination for Associate in Psychiatry and Psychotherapy.—The United States Civil Service Commission announces an examination on August 24th for associate in clinical psychiatry and psychotherapy, from which a vacancy at Saint Elizabeth's Hospital, Washington, D. C., at \$2,500 a year and maintenance will be filled. The appointee will act as consultant to the different medical services of the hospital, and instruct the younger members of the staff in psychological methods and in the technic of case analysis and presentation. He will undertake analytical and therapeutic measures in special functional cases and will be expected to avail himself of the clinical material and laboratory opportunities for special observation and research. It is desired to secure the services of a person familiar with the modern therapeutic movements in the practice of mental medicine, particularly those that have to do with functional conditions and involve the application of psychotherapeutic principles.

A bachelor's degree and an M. D. degree or its equivalent from institutions of recognized standing, at least one year's resident hospital experience, and at least three years' experience in the care and treatment of the insane are required.

Otorhinolaryngologists Meet.—At the annual meeting of the American Laryngological, Rhinological and Otological Society, which was held June 2nd to 4th in Boston, the following officers were elected: president, Dr. Lee Wallace Dean, of Iowa City; vice-presidents, Dr. Harmon Smith, of New York; Dr. Joseph C. Beck, of Chicago; Dr. Joseph B. Greene, of Asheville, N. C.; Dr. William V. Mullin, of Colorado Springs, Colo., and Dr. Hill Hastings, of Los Angeles; secretary, Dr. William H. Haskin, of New York; treasurer, Dr. Ewing W. Day, of Pittsburgh.

New Jersey Medical Meeting.—The Medical Society of New Jersey held its annual meeting June 16th to 19th at Spring Lake, under the presidency of Dr. Gordon K. Dickinson, of Jersey City. The following officers were elected: president, Dr. Philander A. Harris, of Paterson; vice-presidents, Dr. Henry B. Costill, of Trenton; Dr. James Hunter, Jr., of Westville; Dr. Wells P. Eagleton, of Newark; corresponding secretary, Dr. Harry A. Stout, Wenonah (reelected); recording secretary, Dr. William J. Chandler, of South Orange (reelected); treasurer, Dr. Archibald Mercer, of Newark. The next meeting will be in Atlantic City.

Annual Meeting of the Public Health Association.—The American Public Health Association will meet in San Francisco, Cal., September 13th to 17th. Special cars will leave Boston and New York on Tuesday, September 7th, connecting with a special train leaving Chicago on September 8th. The program will include the following: A symposium on the relative functions of official and nonofficial health organizations; Western health problems; narcotic control; food poisoning; organization for child hygiene; mental hygiene; health centres. The foregoing subjects and others will be distributed among the following ten sectional groups: General sessions, public health administration, laboratory, vital statistics, sociological, sanitary engineering, industrial hygiene, food and drugs, personal hygiene, and child hygiene. Detailed information may be obtained from the secretary of the association, Dr. A. W. Hedrich, 169 Massachusetts Avenue, Boston.

—◆—

DIED.

BUCHANAN.—In Toms River, N. J., on Tuesday, July 13th, Dr. Thomas J. Buchanan, aged sixty-one years.

ELLINGWOOD.—In Pasadena, Cal., on Sunday, July 4th, Dr. Finley Ellingwood, of Evanston, Ill., aged sixty-eight years.

GUINNOCK.—In Philadelphia, Pa., on Friday, July 9th, Dr. William H. Guinnock, aged forty-two years.

HIRSCHFELDER.—In San Francisco, Cal., on Saturday, July 3rd, Dr. Joseph Oakland Hirschfelder, aged sixty-six years.

MACGRATH.—In Quincy, Mass., on Sunday, July 4th, Dr. Thomas H. MacGrath, aged seventy-three years.

PARKER.—In Springfield, Mass., on Thursday, July 8th, Dr. Ernest K. Parker.

PELHAM.—In New York, N. Y., on Friday, July 16th, Dr. Mathilde Annette Pelham, aged fifty-six years.

ROBINSSON.—In Alaska, on Sunday, June 27th, Dr. J. T. Robinson, of Columbia Falls, Mont.

STEELY.—In Pocatello, Idaho, on Sunday, June 27th, Dr. Oscar B. Steely, aged fifty-eight years.

Book Reviews

DISCOVERED BY THE CENSOR.

The Cream of the Jest. By JAMES BRANCH CABELL. New York: Robert M. McBride & Co., 1920. Pp. ix-280.

Beyond Life. By JAMES BRANCH CABELL. New York: Robert M. McBride & Co., 1920.

These strange seekers of impurity who from time to time tell us what we should not read, deserve much credit. Not that they tell us what we should read or suggest that we read at all for that matter, but this time they have discovered an American writer who has spoken too freely of things that they insist should remain unsaid. And so the censor has finally proved his value, for he has rendered a service to those of us who managed to secure a copy of the much discussed *Jurgen*. This led on to the discovery of the other books of this young, yet prolific writer. It was with amazement that we found ourselves deeply buried in the master works of American literature.

Slowly, reluctantly, the critics, in spite of their good training, have come to acknowledge Cabell as one of the really great writers of the present day. They attempted to trace back to their source the singing lines of subtle phantasy and a galaxy of writers from Voltaire to Shaw have been assigned as the foster parent. For if credit were to be given an ancestor should be found, for even critics seek legitimacy. And so they took the opportunity of showing their erudition and all the really good books they had read. Meredith, Anatole France and a host of others were given due credit. But why stop by the wayside and discuss the critics? Cabell does this very thoroughly in *Beyond Life*. Without attempting an analysis one can discern a varicolored literary background in the work of this newly discovered American genius.

His earlier works, charming creations of phantasy, yet built on a solid conscious foundation, send the mind scampering back to the historical and literary works of the time of chivalry and gallantry, and prove to us that he has made use of much that we have forgotten. Here, too, we find a promise of what is to come, and indeed they are a fitting prologue to his greater works, *The Cream of the Jest* and *Jurgen*. One immediately forgets the ornate trappings of the holiday editions of Harper's and spends refreshing hours with the charming figures created by Cabell. *The Line of Love*, *Chivalry* and *Gallantry* comprise this series. These tales are fittingly dedicated to that kindly old lady Mrs. Grundy. He probably had his early childhood difficulties with her and had the feeling that he should at least be polite to her, even if, in his maturity, he has discovered her not to be a kindly old lady but a blatant humbug.

When Cabell becomes critic, as he does in *Beyond Life*, he for the first time lays himself open to criticism. While the book is one of the keenest observations on literature and a masterly defense of the use of phantasy in fiction, he attempts to rationalize his method of procedure by proving that true literature should be about things as they should be and not about things as they are. If he would only

go a step farther and show that the phantasies of man, whether they are the myths of the people, the tales in the *Bible*, or the legends that have been handed down in the folk tales for generations and lost in the mists of antiquity, are only the wishes that man has symbolized because he has not been able to bring them into being in the world of reality. To defend these as the ultimate goal of literature is only defending human weakness. True, man in the past has grown by being an ape to his dreams, but the process has been one of a blind groping in a little understood world—the unconscious. Now that we can explore this world and bring it into the world of reality, a tangible, useful thing, how much more rapid should our progress be. The magic worlds woven by the unconscious to satisfy the censor will always remain a source of supply for the poet and creator of literature, but by the very act of his bringing them to us he enters into the world of reality, and we go a step ahead, understanding their creations better, and yet never losing sight of their beauty; indeed they will have a new charm, for then they will be both music and food to us.

It may all be true that realism is not art. Be that as it may, whether we agree or not is small matter, but we have often seen that reality graphically portrayed frequently causes changes by which things became more nearly what they should be instead of what they were. We might mention Harriet Beecher Stowe's *Uncle Tom's Cabin* or Upton Sinclair's *Jungle*, or Chekhov's *Sakaline*, the story of Russia's Siberian prison camp.

After all Cabell's works need no apology nor his own adroit rationalization. They are quite capable of standing by themselves just as many other symbolic masterpieces have stood through the centuries. The question of realism we shall only bring up by alluding to a concrete example. In the *Bible*, which we are told by Cabell is a master work of phantasy and which he rightly chooses to find more easy of belief than many of the events in everyday life, we find the story of the betrayal of Christ by one named Judas. A Russian writer, Andreiff, has made bold and written the story of Judas Iscariot as he interpreted the character from the biblical version. The story of Andreiff may well be called nearer realism than that of the biblical version. His Judas lives and breathes, becomes a powerful character, an unforgettable man, and yet he is the dream Judas of Andreiff, a creature formed in his own unconscious, his interpretation of the symbolic Judas of the *Bible*. He is presented to our conscious minds for reinterpretation. This same sort of thing Cabell has done when he has woven together the dream stuff in his unconscious—the dream material he gathered from the world's myths and legends, regrouped them in a new symphony of phantasy and presented them to the cadence of a new music with a new rhythm. But all these dreams are, as he strives to tell us, a method of escape from the world of reality which he found sordid and uninviting. But always he returns from his world of phantasy and brings back his wanderings to the world of

reality from which there is no escape. He does this in the *Cream of the Jest* and again in *Jurgen*. The skill lies in his ability to do this and not create an anticlimax. Is it escape that he seeks in his journeys in the realm of phantasy and does he try to justify his retreat by pointing the utility of his wanderings? By recalling our ability to ape our dreams and so make progress? Or does he knowingly enter into this semisomnolent dream world in a conscious endeavor to find what his unconscious is creating, to bring it to us as a dream of what men should be instead of what they are? A little of both, perhaps.

In *Beyond Life* Cabell carelessly dismisses Russian literature as dull. Without doubt he made an unfortunate choice and selected examples from a limited field, for they more nearly present the things Cabell most earnestly pleads for. He defends symbolic writing and little realizes that many Russian writers also have their moments of retreat which are marked by the production of some of the finest symbolic productions known in literature. They too have found realism hard to face, and perhaps they are more justified in their complaint than those living in more fortunate surroundings. They had a censorship to face more powerful than the one that suppressed *Jurgen*. They were forced to resort to a subtle, somewhat conscious symbolization in their literature. We find Andreiff writing plays of power and flexibility of almost pure symbolism, such as *Savva*, *The Life of Man*, *The Black Maskers*. Checkhov has given us *Uncle Vanya* and *The Sea Gull* and other plays similar to those of Dunsany. We find Korolenko's phantasy tale, *Makar's Dream*, and Dostoievsky's *Dream of a Queer Fellow* and the dream tales in Tchernechevsky in his book on *What's To Be Done?* and then the story of Grigorovitch, *Karalin's Dream*. In all of these tales the authors make use of carefully worked out symbolisms to describe the world as it should be and not as it is. In spots they do come to earth, even as Cabell, and for the advantage of contrast tell of the world as it is. All these men, and a host of other writers, have handled symbolisms with an understanding that many psychological students of the present day find difficult to grasp. If Cabell had read as deeply of the Russian as he had of the French and English he would not so hastily bring up the issue, and he would not seek so vainly for the things he complains at not finding.

In his attempt to explain that true art is an escape from reality he proves that an understanding of reality is necessary to art. For it is only when we fail to face reality that we seek an escape in the world of phantasy. Here we can soar to our heart's delight and hurl our darts against the world we call distorted. We are likely to forget that if we did not carefully consider and appraise this world of reality and make our judgments after contact we could not fling our satirical darts with any degree of accuracy. In the continuous change occasioned by evolutionary processes and with the many interrelated complexities there are bound to be many maladjustments. These incongruities will always

serve as receptors for the art and criticism of the maladjusted. We will find at every turning these warriors, deriding the world as they find it, behind a shield of wit with their weapons of irony. They find the many weak spots without difficulty and so cover their own inferiorities. The compensatory process is obvious. But withal we owe them much, for with their sharpened wits they hold the mirror to our deficiencies. And so we owe a debt to the Molières, the Nietzsches and the Cabells. More successful beings blinded by the easy adjustments they have made—satisfied with the world they find no difficulty in facing—even for a mediocre existence—satiated with simple pastimes, fit in their flexible souls in an order that could well be improved.

So we find so-called psychologists busily branding as abnormal all those who do not conform—all those who rebel. Perhaps they are right, but these moulded pedagogues forget the debt they owe these malcontents in the world of science and literature. The very things these learned men hurl at the heads of the malcontents are the findings of predecessors of these same grumblers, for it is by the keen wits of the maladjusted that progress is made. Smug critics from their mediocre pathways, often by sheer force of number, bear down upon the seekers of change, for the majority find it more comfortable to conform, and so the conflict goes on. Many take up the popular cry against progress to gain popularity. They travel the easy pathway of conformity. We find these parrots in the pulpit and read them in the press, and then a new outburst from the maladjusted and a new series of popular cries.

So we hail Cabell and bid him sing on. We will try to follow his melodious lines and interpret as best we can the world as it should be—or as he thinks it should be. But we will always enjoy and be grateful for the things he has given us. We greet Cabell and place him in a field alone in English literature. A place of his own creation and far above any of his nearest contemporaries. For he is a true artist. Perhaps the censor may sometime have another surprise for us. He may discover another artist who will rival Cabell.

PRIMITIVE SOCIETY.

Primitive Society. By ROBERT H. LOWIE, Ph.D., Associate Curator of Anthropology, American Museum of Natural History. Author of *Culture and Ethnology*. New York: Boni and Liveright, 1920. Pp. v-463.

The luminousness of Dr. Lowie's study of social foundations is the more remarkable since he has undertaken so vast a subject. The social scheme of primitive races engages each student in a different fashion. But by far the majority limit themselves to a single phase, or when their range of interests happens to be wider, present a report which deteriorates into instances and observations. Tribal peculiarities and customs, privileges and taboos conspire to impress us with the social complexities surrounding the savage, yet the why and wherefore is nowhere touched upon. This Dr. Lowie does not seek to do either, in fact he feels that psychologists and Freudian students should keep their impious hands off the simple, untrammelled savage in their efforts at world analysis.

"(Freud) paints the subjective state of mother-in-law and son-in-law with the lurid colors that tinge our modern family life but are wholly lacking in the savage relationship," says Dr. Lowie, but he himself is still content to note that such peculiar antagonisms exist among the peoples he is studying and does not seek to explain traditions at least as complicated as our modern ones.

For the students of cultural history, for the lay reader who cares to read something a little different from the popular history or a heavy, scientific treatise on primitive man's eccentricities, and for all specialists in the study of human development, a textbook and inspiring guide is here offered. Dr. Lowie's concept of society is that of an interrelation between individuals and groups, therefore to him society is a living, moving whole, as vital as the living beings comprising it. The anatomical structure, marriage, the family, kinship and the sib, law at its very source, the club, caste, and government, all these he presents to us, embryos, as it were, of the social structure that we know today.

The time will come when the anthropologist will find that the material he has been classifying and pigeonholing has more than a historical value. When he begins to explore the human mind, primitive or modern, it is all the same, he will find his observations and stores of data strangely interpretive, not of cultural trends, borrowings of custom between tribes, but of psychic, universal growth. Then perhaps he will be able to tear down the statistics laden structure of modern anthropology and acknowledge himself ready to learn to construct from fundamental causes rather than to distribute his findings under convenient headings. Lowie is still distributing. But he at least believes in a society that is alive.

INSTRUMENTAL ORTHOPEDY.

De l'Orthopédie instrumentale. By Dr. GABRIEL BIDOU. Twenty Full Page Illustrations. Paris, France: The Orphan-Apprentice-School, 1919. Pp. x-132.

The secret of Dr. Bidou's instrumental orthopedy is coadaptation, cooperation, and a thorough knowledge of anatomy on the part of the orthopedist. Most frequently the disabled man has to adapt his whole anatomy to the new limb, often creating a contortion nonexistent before. By the aid of the arthrometer the aid becomes a normal part of the body and demands no extraordinary muscular exertion. He deprecates the use of any stock mechanism, for that which will help one man may be totally unfitted for another. The mechanic begins his work when the mechanical physiology has been thoroughly studied. Some psychology is necessary to earn the good will of the patient toward instrumental aid and to teach him to collaborate with the surgeon, to conquer inertia, persevere in spite of fatigue, and overcome mental apathy, because this resignation to impotency is itself a fault. He relies on compassion, help, from family or State, as on a crutch and no longer exerts himself. It is impossible to give evidence by words only. Let those who want to understand that which is a hopeful remedial attempt to scientifically help our disabled study the lucid book by Dr. Bidou.

BRITISH MEDICAL ASSOCIATION.

British Medical Association. Proceedings of Special Clinical and Scientific Meeting, London, April 8-11, 1919. London: The British Medical Association, 1919. Pp. vii-403.

The papers presented here are those of a special clinical and scientific meeting held by the British Medical Association April 8 to 11, 1919, in London, under the presidency of Sir Clifford Allbutt. The last of the customary general meetings had been in 1914, and after the armistice it was decided to hold a meeting with a smaller number of sections than usual and at an early date, so that foreign medical officers might attend before their return home. The material is given under three heads, medicine, surgery, and preventive medicine and pathology. Reports of discussions are included. There are two general addresses, one by Sir Clifford Allbutt on the New Birth of Medicine, and the other by Sir Cuthbert Wallace on the Rise of the Casualty Clearing Station. Various war records are appended.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

GREEN RUST. By EDGAR WALLACE. Boston: Small, Maynard & Co. Pp. i-299.

THE PATHWAY OF ADVENTURE. By ROSS TYRRELL. New York: Alfred A. Knopf, 1920. Pp. vii-310.

THE PARADISE MYSTERY. By J. S. FLETCHER. New York: Alfred A. Knopf, 1920. Pp. ix-306.

FOLLOW THE LITTLE PICTURES! By ALAN GRAHAM. Boston: Little, Brown & Co., 1920. Pp. iii-299.

THE VANISHING MEN. By RICHARD WASHBURN CHILD. Author of *Velvet Black*, etc. New York: E. P. Dutton & Co. Pp. i-324.

WOMAN. By MAGDELEINE MARK. Introduction by HENRI BARBUSSE. Translated by ADELE SZOLD SELTZER. New York: Thomas Seltzer, 1920. Pp. vii-228.

SEX AND SOCIETY—STUDIES IN THE SOCIAL PSYCHOLOGY OF SEX. By WILLIAM I. THOMAS. Seventh Edition. Boston: Richard G. Badger. Pp. vii-325.

THE IVORY DISC. By PERCY JAMES BREBNER. Author of *A Gallant Lady*, *The Turbulent Duchess*, *The Little Grey Shoe*, etc. New York: Duffield & Co., 1920. Pp. iii-254.

THE MYSTERY IN THE RITSMORE. By WILLIAM JOHNSTON. With Illustrations by HAROLD JAMES CUE. Boston: Little, Brown & Co., 1920. Pp. i-293.

SANE SEX LIFE AND SANE SEX LIVING—SOME THINGS THAT ALL SANE PEOPLE OUGHT TO KNOW ABOUT SEX NATURE AND SEX FUNCTIONING; ITS PLACE IN THE ECONOMY OF LIFE, ITS PROPER TRAINING AND RIGHTEOUS EXERCISE. Also, *A Study of How to Cultivate and Practise the Art of Love, and How to Master the Science of Procreation.* By H. W. LONG, M.D., Captain, M. R. C. Boston: Richard G. Badger. Pp. xxii-151.

HELMETS AND BODY ARMOR IN MODERN WARFARE. By BASHFORD DEAN, Ph.D., Curator of Armor, Metropolitan Museum of Art, formerly Major of Ordnance, U. S. Army, in Charge of Armor Unit, Equipment Section, Engineering Division, Washington; formerly chariman of the Committee of Helmets and Body Armor, Engineering Division of the National Research Council. Illustrated. New Haven: Yale University Press. London: Oxford University Press, 1920. Pp. xxiii-325.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

RECENT GLEANINGS IN DIPHTHERIA PROPHYLAXIS.

BY LOUIS T. DE M. SAJOUS, B. S., M. D.,
Philadelphia.

(Continued from page 917, Vol. CXI.)

What of the administration of antitoxin in an attempt to rid diphtheria carriers of their infection? The generally accepted view of the action of antitoxin is that it is limited to the neutralization of diphtheria toxin and that the remedy has no direct effect on the diphtheria bacilli themselves. Such being the case, antitoxin should be valueless in the treatment of carriers. Yet it has been noted, according to McCollom and Place, 1913, that chronic nasal diphtheria will often clear bacteriologically as soon as the existing slight toxin irritation has been eliminated through antitoxin administration. From personal experience I am not convinced that antitoxin is wholly useless in the treatment of the average carrier. Indeed, the impression has been gained that, in some instances at least, antitoxin administration even in small doses may result in some change in the morphological features of the organism and its removal from the group of highly virulent, culturally positive bacilli. If such is actually the case, antitoxin administration might be considered at least worth trying in troublesome carrier cases.

Again, attempts have been made to overcome the carrier state by awakening an active immunity in the carrier through injection of killed diphtheria bacilli or toxin. Thus, in 1912, Petruschky treated a small series of cases, including some convalescents from diphtheria, with injections of diphtheria bacilli killed by chloroform vapor. The majority of the cases soon became negative—in five to twenty-nine days—but in one instance negative cultures were obtained only after intermittent treatment occupying over a year.

In an attempt to overcome protracted carrier infection in diphtheria convalescents by inducing a further defensive reaction in the body tissues and fluids, Hewlett and Nankiwell, 1912, administered injections of diphtheria endotoxin, prepared by collecting a growth of virulent diphtheria bacilli from culture media, removing the toxin by washing the growth two or three times in sterile saline solution, grinding the bacterial mass in the presence of intense cold, and filtering the ground mass through a Berkefeld filter. The resulting filtrate, which contained the endotoxin, was then standardized by addition of sterile saline solution in such amount that the product contained from two to five milligrams of the endotoxin per mil of fluid. The most effective plan of administration, clinically, was found to be to give an initial dose of two milligrams of the endotoxin and, if the cultures remained positive for a week or ten days, to give another dose of five milligrams, to be repeated later if necessary. Of

twenty-four diphtheria carriers in whom this measure was applied, all showed improvement after one or more endotoxin injections. Many of these persons had continued to be carriers for a number of weeks or months after the acute attack of diphtheria. After the endotoxin injections the carrier infection ceased entirely in many cases, while among those in which complete success was not attained there was at least a reduction in the number of bacilli in all instances. Reaction following the injections was limited to some local redness and tenderness, and in one case only, malaise and an evanescent rise of temperature. The doses of the endotoxin administered to adults and children were the same. On the whole, it must be admitted that no completely satisfactory procedure for eliminating carrier infection has as yet been discovered.

In some instances the inconvenience of isolation rendered necessary by carrier infection may be cut short by the use of the guineapig test, performed to ascertain whether the germs continuously harbored in a given case are actually of high virulence or are of so low a grade as to constitute no menace to susceptible contacts. Where the guineapig into which the germs are injected fails to succumb, the infection is considered to be one of low virulence and isolation of the carrier no longer insisted upon.

Administration of immunizing doses of antitoxin to the house contacts in clinical diphtheria cases is generally considered an important step in prophylaxis. Although some authorities would limit such immunization to contacts in special institutions for children and in hospitals, and depend upon careful watching of the contacts for signs of incipient clinical diphtheria, to supply the necessary indications for early, curative antitoxin administration, the fact remains that in the average household such expert watching is impracticable, and proper prophylaxis imperatively requires antitoxin injection in the other members of the household, particularly children, and in less degree young adults. Although secondary cases of diphtheria in a household are not very common, they do occur, and by prophylactic immunization of the other members of the family the number of these cases can be very markedly reduced. Results from antitoxin immunization in hospitals and other institutions preclude all doubt as to its preventive value. Thus, McCollom and Place, 1913, note that before immunization was applied, outbreaks of diphtheria were very frequent among the young children in the Infants' Hospital, Boston, as well as among the nurses and nursery maids. In a number of years after the institution of immunization, on the other hand, but one case of diphtheria probably originating in the hospital, developed among the infant inmates; a number of nurses and nursery maids did contract diphtheria, but these were all comprised among those who had declined to be immunized. The same authors note that in another institution, in which scarlet fever patients

are cared for, antitoxin immunization brought about cessation of diphtheria outbreaks in the wards.

These represent typical instances of experience with antitoxin immunization, though some observers appear to have been less fortunate—possibly owing to the use of an inferior quality of antitoxin, insufficient dose, or certain unusual circumstances among the classes of patients immunized. Thus Markuson and Agopoff, 1911, reported disappointing results among 1,178 children suffering from measles, in whom antitoxin was given to prevent diphtheria. Brown, Allen, and Lupton, 1907, stated that among 129 tuberculous and forty-nine nontuberculous individuals to whom 400 immunizing doses of antitoxin had been given during an epidemic, four patients had developed diphtheria between the fourteenth and sixteenth days following the first antitoxin injection, and in one case four days and in another one day after a second injection. Blumenau, 1911, stated that among 348 children with measles or scarlet fever to each of whom two injections of 500 or 600 units of antitoxin had been given in nineteen, or 5.5 per cent., diphtheria had developed later, and the procedure of immunization had been changed to active immunization with diphtheria toxin.

(To be continued.)

Treatment of the Postmature Child.—Charles A. Reed (*Surgery, Gynecology and Obstetrics*, June, 1920) states that when diagnosis of maturity or postmaturity has been made it is too late to influence the size of the child by Prochownik's diet except in those rare cases of habitual postmaturity described by Moissard. Here perhaps the conditions could be anticipated. The principle of management must be based on the results of regular and painstaking examinations of the child with a merely subsidiary interest in the subjective history. If the child is mature and the pelvis not seriously contracted, several days or a week may be permitted to elapse, and then if Nature fails in her duty, a day should be set and the labor induced. The induction may be brought about easily, safely, and expeditiously by castor oil and quinine, or by the Voorhees bag, or by both. Castor oil and quinine are effective in possibly two cases out of five but the Voorhees bag is always highly dependable.

If the attendant has not been watchful or if through the weight of tradition he has allowed the child to become postmature, a careful revision of the pelvic diameters must be undertaken. This examination may show that the transit of the child through the maternal passages would be highly questionable and possibly accompanied by more than ordinary danger. In such a case the Cæsarean operation will suggest itself as the most conservative way of terminating the pregnancy. On the other hand if the delivery by the pelvic route seems feasible, even though difficult, labor may be induced by the bag with a reservation that if the natural powers are insufficient, delivery may be completed by version and extraction or forceps, depending on the conditions and preceded if necessary by pubiotomy. To foresee difficulties that impend and to anticipate them by proper and judicious means is called by rhetoricians a pro-

lapsus. To foresee the obstacles and dangers which attend and follow the birth of a large or postmature child and to avert them by intelligence and skill is good obstetrics. Unhappily or otherwise we all have an ingrained reluctance to intervene in the course of what is apparently a regularly advancing pregnancy. It is much easier to let the business slip along under the impression, born of our hopes rather than of our knowledge, that the problem may solve itself.

Letters to the Editors.

PHYSICIANS IN THE HALL OF FAME.

NEW YORK, July 6, 1920.

To the Editors:

You were good enough to publish my letter in reference to the election of the names of Morton, McDowell, and Sims to the Hall of Fame in your issue of June 26th. In my letter I stated that the election would take place on July 1st. I have since learned that the electors have until October 1st to make their decision, which gives all those who are interested time and opportunity to send their endorsement of all or any one of the candidates mentioned to the electors or to the Senate of the New York University.

Since the publication of my last letter I have received a number of requests to include in the list of America's immortals the great Benjamin Rush, whom Roswell Park in his *History of Medicine* calls "the most conspicuous medical character of the century." American internists will always hold Rush in grateful admiration as an acute observer of disease. His description of clinical phenomena is today as authentic as when published, and, of course, I am glad to include the founder of Rush Medical College among those of our profession who should have a place in the Hall of Fame.

S. ADOLPHUS KNOPF, M. D.

VENEREAL PROPHYLAXIS.

PENNSYLVANIA DEPARTMENT OF HEALTH,
HARRISBURG, June 19, 1920.

To the Editors:

A word of appreciation for the editorial on the venereal peril published in the June 12th issue of the NEW YORK MEDICAL JOURNAL. Notice is taken of the mention made of sixteen prophylaxis stations established by the Department of Health.

The Pennsylvania State Department of Health does not centre its activity in the matter of venereal prophylaxis upon stations where prophylaxis may be given but upon the individual prophylaxis package, which is, or should be, obtainable at all drug stores. The department puts its approval upon preparations which come up to specifications as regards bactericidal properties, nonirritative effects, contents of the tube, character of the container, etc. Letters have gone out to all druggists in the state asking them to keep in stock those preparations which come up to the requirements of the department. I wish to say that the prophylaxis stations are not doing much in this line of work.

THE ANATOMICAL AND PHYSIOLOGICAL THEORIES OF PLATO.

BY JONATHAN WRIGHT, M. D.
Pleasantville, N. Y.

It is quite evident (8) that the Homeric Greeks entertained ideas in regard to the pneuma and the soul of man but little removed from the accounts travelers give of those of primitive man. Man was in relationship with his environment by virtue of it. His ideas were essentially pantheistic. It was the pneuma within the body which not only commanded its activities but translated its impressions. It played the part not only of the sensory nerves, but of the motor nerves as well. It went in and out of the body in respiration. In the phenomenon of death, it escaped permanently through the air passages or through any gaping wound of the body that let it out. What the Homeric idea of disease was cannot be exactly demonstrated. It was evidently to a large extent, one of demonology, evolving toward a differentiation which in the course of a few centuries almost entirely submerged the primitive etiology, for there is no demonology in Hippocrates. Herodotus (484-424 B. C.) was about twenty-five years old when Hippocrates was born (460 B. C.), according to commonly accepted chronology, and he said Homer lived about four hundred years before his time. Some of the Homeric poems are supposed to have been composed earlier than this, but we are perhaps not far wrong in allowing four centuries in which this striking change took place. Puccinotti (1) has written one of the most readable of all the histories of medicine. The prominence he gives to the Chiron School of Medicine from which Achilles and some other Homeric heroes graduated, and the still more vague emphasis he places on the University of Orpheus, more recent archeology has failed to justify.

Æsculapius may have had an honorary LL.D. of the former, for he sent his two sons to the Trojan War, not as warriors alone, but as physicians. One has to be a little cautious in seeing any affiliation of the doctrine of the pneuma with the deification of Æsculapius, to be inferred from a story of the traveler Pausanias (2) written in the latter part of the second century of our era, when the glories of ancient Greece were long since things of the past. He relates (VII, 23) that a Sidonian told him that at Tyre Æsculapius was worshipped as the symbol of air, because that element is the father

of health and Pausanias told him the same idea prevailed in Greece. This all may very well have been adapted from the then greatly expanded doctrine, springing from the faddist teachings of Diogenes Apollonius in the time of Hippocrates. In the verses of Orpheus, according to Aristotle (*On the Soul*) the soul is described as moved to and fro by the winds and it is drawn into the body in respiration, perhaps with the first inspiration after birth. Now we infer from Diogenes Laertius (3) that Orpheus was a barbarian and that those who believed that the knowledge of philosophy came to the Greeks from barbarians called him a philosopher. Diogenes calls him a barbarian because he was a Thracian, but Thrace sent forth many minstrels and prophets in the time of Homer and doubtless in the earlier time of the Trojan War. This is by no means the chief intimation we have of the external source of Greek theories, but despite the association of Pythagoras with Egyptians and other Asiatics we may imagine that as heir of Orphic religious enthusiasm he may have had from Orpheus the view he had of the Cosmos "always inhaling and exhaling infinite breath or void (ether) which surrounds it on every side."

We need not, however, seek in the baffling traditions of half mythical persons for the origin of such ideas. It was from the Asiatic Greeks, from the nature philosophers of Ionia and Caria, from Colophon and Miletus, from Cnidos and Cos and the islands that fringe the shores of the Asiatic littoral, in contact with the sea and land routes between Egypt and Asia Minor, over which commerce traveled, that history records Greek philosophy sprang. Xenophanes (flourished 536-496 B. C.) seems to have dissented from the view of Pythagoras (born 608 B. C.) and he is thought by Gomperz (6), with true Teutonic modesty ascribing the origin of the pneuma to the inventive minds of the skin clad barbarians of the Danube, to have received it undiluted from these or more northern Aryans. According to Xenophanes the soul returns to celestial space. A line of Epicharmus of Cos, a contemporary of Xenophanes, has been preserved to us, bearing the same sentiment, strangely modern in form: "Dust to dust and breath of Heaven."

This brings it direct to Cos, the birthplace of Hippocrates who was ten years old at the reported time of the death of Epicharmus (450 B. C.). Though it is first found surviving in the text of Herodotus, Xenophanes of Colophon is said to have

been the first to employ the word *pneuma* in this connection. We have Fuchs's (6) word for it that in Homer the substantive form is not used. Dar-emberg (7) though asserting the existence of the idea of the *pneuma* in Homer, which we have verified (8), supposes the word to have been derived from that which in Homer included a reference to both lungs and pleura. Anaximenes of Miletus must have belonged to this epoch also. The single fragment of his philosophy which has come down to us in his own words concerns us at once. "Just as our soul, being air, holds us together, so do breath and air encompass the whole world." (9) We might trace this doctrine through its modification into the *nous* by Anaxagoras, the pupil of Anaximenes, and to Athens through Diogenes Apollonius, who may have written the book on *The Winds* in the Hippocratic Corpus, where it is carried to absurdity.

In Plato the fire of Heraclitus, which in Aristotle became the vital heat, is worked into a wonderful cosmic theory with the air and water, which few can comprehend. Perhaps Plato took some of the obscurity of Heraclitus into this part of his writings, most of which are as clear as crystal. At any rate we get the trail from the nature philosophy of Anaximenes and Heraclitus, straight into the dark shadows of the *Timæus*, where we find the *pneuma* theory which was transmitted from this work of Plato, rather than from any genuine treatise of Hippocrates, into later medical literature. It flourished in the time of Hippocrates, but despite the easily found traces of nature philosophy which probably came through Alcmaeon and Empedocles, we get no distinct formulation of the *pneuma* idea in his genuine works and but little incidental indication that he was seriously influenced by it. For these reasons I for the present pass over the older Hippocrates to his younger contemporary Plato and the latter's great pupil, Aristotle. In Plato the fire still retains the mark of its protagonist, Heraclitus, and this part of his doctrine we may well associate with that of the Persian Zoroaster. According to Martin (10) Galen or the author of the tract on philosophy, usually incorporated in his works, and the ancient critics, Proclus, Chalcidius and others asserted the meaning of Plato was that the soul was incorporeal. Hence it had to be separated from the air. Unless that is the meaning of Plato's tendency to give prominence to the ether, I cannot see it in that light. The idea of the air as a corporeal body, perhaps only emphasized by the experiment of Empedocles and long admitted, was still invisible and mysterious. Later the stoics, especially Chrysippus, placed themselves firmly on the basis of primitive man and identified the soul with the air, claiming the support of Plato. In his view it was allied with fire and ether, one of which was grossly misconceived and the latter still is a theory. It seems to me that Plato nowhere frankly separates either the fire or the ether or the soul from the air. Rigid analysis had not become a habit of mind. There are passages in Plato which later philosophers were accustomed to read as though they refer to the corporeality, to the reality of the air. In

their time, doubtless they felt justified in excluding the soul from the congeries of conceptions still adherent to the air, but there is in Plato no clearly cut idea that it had nothing to do with the air. Galen (18) declares the *Timæus* was read only to a few friends capable of understanding it. He intimates that the pantheistic doctrine it contains was unknown to the common people and might offend them. Galen refers rather to this doctrine of the soul as puzzling than to Plato's remarkable conception of the animal body.

Importance in medicine was first given to the *pneuma* by Philistion of the Sicilian School (11). From him Plato may have derived his doctrines when he went to Sicily on his unfortunate errand as tutor of Dionysius II, though the *Timæus* and many of his earlier works may have been written before. Wellmann attributes to Diocles the first distinction made between arteries and veins, both carrying air as well as blood according to the view of the Sicilian School. For Diocles, younger than Hippocrates, and to a less extent for Plato, the *pneuma* disturbances were combined with disturbances in the equilibrium of the humors as the cause of disease. Thus early the humoral doctrines and those of the *pneuma* were combined in medical conceptions of etiology. Plato repeats the age old conception in the *Timæus* of the impressions on the body being distributed by the blood vessels, but it is not clear whether they are inherent in the blood or in the air mixed with it. The importance we ascribe to finding such a discrimination (12) is perhaps not very consistent since in modern times we see no difficulty in ascribing a lot of properties to the blood in serotherapy, without considering or without knowing in chemical terms just what formula represents any specific attribute.

To discuss further Plato's ideas in regard to the soul would involve the exertion of higher powers than my own. They receive an enormous expansion in his dialogues, taken as a whole, and libraries of books have subsequently been filled with comments on them. I must confine myself to the bearing these ideas have upon the *pneuma* chiefly in its relation to the conceptions of the anatomy of his time and briefly in its influence on the succeeding epochs in physiological science. I may make an exception to this limitation by briefly alluding to the threefold partition of the soul—the noble cogitations of the intellect being seated in the brain, a relic of the ancient doctrine of Alcmaeon, the noble emotions in the heart and the animal appetites and passions in the abdomen between the diaphragm and the navel. We see thus the multiple souls of the primitive African philosophers finding in the human frame a separate habitation. It was into Sicily years before Plato and two thousand years after him that Africa continued to pour, by invasion and by commerce, her hordes from Carthage and the neighboring shores of her Mediterranean coasts. Plato is said to have traded with Egypt in olive oil, as Solon did before him. I think I have shown (13) that we have sufficiently clear evidence in the Papyrus Ebers that *pneuma* ideas dominate its anatomy and physiology,

and I have elsewhere (14) cited at some length from the copious evidence ethnology offers of the widespread belief in multiple souls by primitive people. This is especially abundant in savage Africa in modern times. With these primitive conceptions of the soul we find, added to that of the pneuma from Egypt, Plato's obligations to Heraclitus for the Asiatic theories of fire and perhaps of the ether, the former finally evolving into a form, that of heat, which in Aristotle allies it more definitely with the principles of modern science. These facts stand forth, thanks to the labors of many commentators, ancient and modern, in an attentive study of the *Timæus*. This book has baffled the most skillful of translators and the most profound of critics. Perhaps its obscurity is one reason for the influence it had on the subsequent evolution of medicine. The literature¹ which has grown up around the *Timæus* has displayed the unequalled scope and power of the imagination of Plato.

No imagination is purely imaginary. Every castle in Spain has its foundation in the solid facts of real life. Every dream, we are told by those not devoid of an ill controlled imagination themselves, has its root in the impressions made on the mind by the senses of men when awake. We may be sure that Plato did not evolve from his inner consciousness alone that fantastic idea of anatomy and physiology in those parts exhibiting the involvement of the pneuma, set forth in the *Timæus*, to which I can scarcely do more than allude. Cicero's far less profound mind adopted much of it in his essay on the *Nature of the Gods* (Lib. II, 54-56), and it is there somewhat incompletely but more clearly set forth. Professor Jowett conferred a great benefit on medicine by opening to modern readers the dialogues of Plato in an English translation. Of this Sir William Osler (15) took advantage many years ago in order to offer to the attention of medical men those points of medical interest which they contain. Unfortunately the brilliant performance of Jowett is obscured in the inadequate and often incoherent rendering of this part of the *Timæus*. Martin (10) is considerably more successful, but a comparison of either the English or the French interpretation with the Greek text will easily reveal an inexactitude which is not compensated for by their plausibility and which evidently arose from bewilderment in both translators, partly due doubtless to their insufficient acquaintance with the general outlines of human anatomy and physiology and the history of their evolution. Chiefly, however, one must realize it is due to the remarkable scope of Plato's thought and the wide expansion of his imagination. Possibly by approaching it from a viewpoint formed by a better knowledge of medicine and by a better understanding of the course of medical thought before and after Plato, the medical reader, despite

his vastly inferior philological knowledge, may arrive at a more satisfying if not a more accurate and technical understanding of Plato's thought.

In the spurious book on the *Aliment* we have seen (16) the idea existent, probably at least as early as Plato's years of activity, that the air is a food when inspired. We must bear in mind that however faulty the idea of the circulation of the blood was for the contemporaries of Plato and for those living nearly 2000 years after him, it did surge with the air through the veins and, for some, through the arteries. If the air is a food to the tissues it must get to them by channels at that time, undiscovered either in the lung or the system generally. No such mind as Plato's could rest satisfied with this gap of nutrition in the continuity of the ever changing flood of existence as conceived by Heraclitus. We may imagine that in the *Timæus* Plato followed the old Egyptian conception of channels (or metie) running everywhere through the body. We are able to help ourselves out with the lymph spaces and call them channels (or metie). But Plato had no such knowledge as we possess. What must have occurred to him was: "It seems evident that thus the nutrition and the life is carried throughout the body, but how does it reach the flesh lying between the vessels we see?" Plato therefore conceived of the life—of the air and fire (heat?) passing through the veins, but also God wove "together of fire and air like basket nets" [78]—a sort of reticular tissue we may call it for a moment in order to encourage modern anatomists. We shall find this tissue of Plato's imagination dissolving and flowing through itself. Modern histologists know of the cells wandering off from the walls of the lymph spaces, and know that it is a structure in which the constituents flow away and are replaced by others, the ever changing river of life, as old Heraclitus thought of it, which is never the same—"man never steps twice in the same river." I am not trying so much to force a parallel of things as to exhibit the underlying parallelism of thought between Platonic and modern mental concepts.

In the discourse of Plato we get a hint of this transmutation of tissue—of the flesh into liquid "which generates all sorts of bile and lymph and phlegm," in the process of disease. It is perhaps not necessary to use modern parlance in tracing the genesis of mucus and pus. Something happens in the retiform tissue; a blow, a foreign body, a bacterium, whose potentiality is so interesting to us, cause the network to break down into a fluid, which flows away along lymph channels if no surgeon is at hand. The pathological change as well as the physiological change which took place was thought of by Plato. "Now everyone can see whence diseases arise. There are four natures out of which the body is compacted—earth and fire and water and air, and the unnatural excess and defects of these, or the change of any of them from their own natural place into another, or again, the assumption on the part of these diverse natures of fire and the like of that which is not suitable to them, or anything of the sort, produces diseases

¹ Léon Robin has recently published an interesting study on the physics of Plato (*Études sur la signification et la place de la physique dans la philosophie de Platon*) which has come to my notice since this article has been written, but there seems to be little in it in regard to matters of our especial interest—nothing, I think, which I have failed at least to allude to here. I cannot, however, too highly recommend it to the students of physics proper in the *Timæus* and to lovers of Plato in general.

and disorders; for each being produced or changed in a manner contrary to nature, the elements which were previously cool grow warm, and those which were dry become moist, and the light becomes heavy, and the heavy light; all sorts of changes occur." I doubt if my readers will think it worth while to follow the thought in this, but it is little worse than the mist which hangs about the beginnings of bacteriology or serology. It is less difficult to seize the conclusion which is to be drawn from this picture of the processes in the living body, if one gets the drift of the thought of them through the mind of Plato and sees how out of it arises his discrimination of the pathological from the physiological. "For we affirm that only the same, in the same and like manner and proportion added or subtracted to or from the same, will allow the body to remain in the same state, whole and sound, and that, whatever is taken away or added in violation of these rules causes all manner of changes and infinite diseases and disorders."

Now this gives us a glimpse of the grasp Plato had of the many theories of the nature of man and his diseases prevalent in his day, which is a little aside from the subsidiary theme of the reticular tissue which has led us in sight of it. The modern reticular network like the Platonic has a need for renovation and repair. Everything wore out in his day as it does in our own. Everything now, as in the days of Heraclitus, is in a state of flux, but it is a proposition hard for us to grasp when, as we shall note, we realize that Plato made his air and fire framework to flow along the channels of the body to aid in vivifying and renewing it, somewhat as we make our wandering cells perform their functions. After Plato we find Erasistratus busy with the thought of the connective tissue. He it was who gave it, in the lungs, the name of parenchyma. I do not know if the cryptic sayings of Plato in the *Timæus* had their influence on him. As for the antecedents of Plato's own thought, no fact or fancy can be seized by the intellect of man which is unassociated with anything that is already familiar to him. The only previous hint in antiquity known to me of the body made as a network is derived from an incidental remark of Aristotle (*Generation of Animals* II, cap. 1) who says that the organs of an animal are generated either simultaneously or in successive order as described "in the verses of Orpheus. For it is there said that an animal is generated similarly to the knots of a net." I recognize that the thought of Aristotle is not in line with our present concern, but we get from Orpheus at least the simile of a fish basket or net. In Jowett's translation Plato proceeds thus in continuation of the sentence quoted above, as to a basket network of fire and air, having in mind perhaps a basket such as is used to capture lobsters or fish.

"The network he took and spread over the newly formed animal in the following manner: he let one of the openings pass into the mouth; this opening was twofold, and he let one part of it descend by the air pipes into the lungs, the other by the side of the air pipes into the belly. (The laryngo-

trachea and the esophagus). The other opening (the pharynx?) he divided into two parts, both of which he made to communicate with the channels of the nose, so that when there was no way through the mouth the streams of the mouth were replenished from the nostril. But the other cavity (?) of the network he placed around so much of the body as was hollow, and the entire receptacle which was composed of air he made to flow into the passage of the network, which then flowed back; the tissue of the lung found a way in and out of the pores of the body, and the rays of fire which were interlaced followed the passage of the air either way; this continuing as long as the mortal being holds together. These, as we affirm, are the phenomena which the imposer of names called respiration and expiration." We must pause to recollect that air is passing not alone into the arteries from the modern air passages, but the process includes the passage of air through the pores of the body, which not only channel it but, in the sense of Empedocles, pierce the integument and communicate with the outside air. "And all this process of cause and effect took place that the body might be watered and cooled, and thus have nourishment and life; for when the respiration is going in and out, and the fire (heat?), which follows at the same time, is moving to and fro, and entering through the belly, reaches the meat and drink, it liquefies them, and dividing them into small portions and guiding them through the passages where it goes, draws them as from a fountain into the channels or veins, and makes the stream of the veins flow through the body as through a conduit."

Reflecting on the vicissitudes of the text, passing through hands entirely unskilled and interpreted by minds entirely void of any idea of anatomy and physiology, we may easily conceive how such a passage may have become so mutilated as to be now almost undecipherable by the ablest of philologists and paleographers, but by keeping the central idea of the necessity for the interchange we now know goes on in the lymph channels, we get in hailing distance of Plato's thought. How are we going to account for the birth of this stupefying conception in the mind of Plato? The mind of Plato, we may grant, explains no inconsiderable part of it. Its fertility can be gauged only by reading all his dialogues. For many readers of this article this is an impracticable suggestion, but they can at least assume that he had a mind of exceptional imaginative power. As has already been pointed out no imagination is purely imaginary. It grows by what it feeds upon. So far as space admits, I have attempted to trace some connection between Plato and the thought of his time. He mentions Heraclitus and it is quite clear he was profoundly influenced by his philosophy. Burnet (9a) guided by Proclus, believes Plato knew nothing of Democritus and his atoms. He does not mention him, but one can scarcely believe he was not familiar with his doctrines. Since Aristophanes (17) in the *Clouds* refers to the *Vortex*, the atomic theory must have been familiar to the Athens of the days of Plato. The expression used by Empedocles to describe the movement of the

elements is that they run through each other (fr. 17-34).

The anatomy and physiology of Plato, whatever may have been the sources from which he drew his inspiration, were figments of his imagination. On it he drew for his mental pictures of the structure and forces of the body. The fire being an attenuated form of matter as compared to the coarser particles of air, he made his connective tissue out of them. The reason for the network was not only to permit air and fire and food to flow through the body but to permit the disengaged particles of air and fire to escape while the food and the drink [78 A], the chief nutrition of the body is retained. Their intimate relation to one another while in the body is made plain, the air being thought of as constituting the outer layers of the network and the fire or the heat the inner lining, presumably in contact with the digested food and drink, but their state of flux we recognize as greatly exaggerated in Plato's thought, evidently owing to the emphasis of Heraclitean doctrine. We see also in the mingling of the humors and the pneuma the trace of Sicilian medicine and we realize that like Diocles, Plato was not purely a pneumatist nor purely a humoralist, but admitting the equilibrium of the four elements as a state of health and its disturbance as disease in accord with Alcmaeon, he left the way open to conjecture that the cause of that disturbance of equilibrium might be sought in the pneuma.

AN EPIDEMIC OF TYPHOID FEVER OF WATER BORNE ORIGIN AND CARRIER TRANSMISSION.

*At Camp Hospital No. 10, Prauthoy, Haute Marne,
American Expeditionary Forces, France.*

BY LEON H. CORNWALL, M. D.,
New York,

Pathological Laboratories, City Hospital, Blackwell's Island;
Captain, Medical Corps, U. S. Army,

AND JAMES P. CRAWFORD, M. D.,
San Francisco,

Captain Medical Corps, U. S. Army.

On January 20, 1919, a case of clinical typhoid fever was discovered at Camp Hospital No. 10, located at Prauthoy, Haute Marne, France. The tenth area from which this hospital received its patients was occupied by the Eighty-second division and a few casual organizations. This patient was admitted on January 16th, and for the first few days the condition was diagnosed as bronchopneumonia. On January 24th a crop of rose spots appeared and on the following day a blood culture was taken. At that time the cultural bacteriology for Camp Hospital No. 10 was done at the central medical department laboratory at Dijon, France, a distance of some thirty kilometres. Within forty-eight hours, however, the clinical diagnosis was confirmed by a positive report of *Bacillus typhosus*.

The case originated in Battery E of the 321st Field Artillery and, as the number of men being hospitalized from that organization indicated a high sick rate, a careful watch was kept of all admissions from that command. To facilitate the early diagnosis of typhoid or paratyphoid fever a special building was designated as a gastroenteric ward. By the improvisation of temporary partitions this building was subdivided into sections for: 1, Clinical typhoid fever, 2, typhoid fever suspects, 3, typhoid carriers, and 4, other conditions such as gastritis, gastroenteritis, diarrhea, dysentery, acute catarrhal jaundice and acute cholecystitis. All enteric patients in the hospital were immediately collected here and all new admissions for such conditions were sent to this building for observation.

As a result of a conference between Major John W. Emhardt, commanding officer of the hospital, Major Victor C. Vaughan, Jr., epidemiologist from the division of laboratories and infectious diseases of the office of the chief surgeon, A. E. F., and the laboratory officer assigned to the hospital, the following hospital order was issued:

"A blood culture for typhoidlike organisms will be taken in the case of all typhoid suspects on admission. If negative two more blood cultures will be taken at the end of forty-eight and ninety-six hours respectively. A blood culture will then be taken every seven days throughout the illness, without regard to previous findings. An additional blood culture will be taken at the onset of a relapse. "In cases of fevers of an unknown origin three successive blood cultures will be taken at forty-eight hour intervals following admission to the hospital.

"Fecal cultures for typhoidlike organisms will

be made in all cases of typhoid suspects or fevers of unknown origin of forty-eight hours' duration and in such cases of gastrointestinal derangement as gastritis, gastroenteritis, diarrhea, dysentery, acute catarrhal jaundice, and acute catarrhal cholecystitis, with or without fever, when occurring in a command from which cases of typhoid fever have been reported. If cultures from any of the above mentioned gastrointestinal derangements from normal stools are negative a saline purge will be administered and a second culture will be made from the resulting movement.

"Patients in whose stools typhoid or typhoidlike organisms have been discovered will not be discharged from the hospital to a duty status until three successive negative fecal and urine cultures have been obtained, the same to be taken at weekly intervals.

"A quantitative Widal reaction will be determined at seven day intervals in each suspected and proved case of typhoid or paratyphoid fever."

This necessitated laboratory facilities beyond those possessed by the hospital at that time so a U. S. Army transportable laboratory equipment was requisitioned and immediately secured from the advance medical supply depot at Is-sur-Tille. A portion of one of the hospital buildings was taken over and divided into four small rooms. These were furnished with water, electricity and other equipment, and with the assistance of a sergeant of the medical department, who was a graduate pharmacist, and two trained technicians assigned from the central medical laboratory, the laboratory studies, under the direction of Captain Cornwall, were commenced. Later this laboratory personnel was increased by the assignment of Captain Crawford and four enlisted men, who had comprised the personnel of the Eighty-second divisional laboratory.

Before February 1, 1919, eleven patients had been admitted to the hospital from Battery E, 321st Field Artillery with either clearly marked or very suggestive clinical symptoms of typhoid fever. On February 3rd, two more patients were admitted, on the 7th one, on the 9th two, on the 14th one, and on the 15th one, making a total of eighteen cases of clinical typhoid fever from the same organization within a month.

EPIDEMIOLOGY.

Investigation for the purpose of ascertaining the possible source of the epidemic lead first to an inquiry as to the movements of the organization before it reached the area. It had come from the Argonne region with the other units of the Eighty-second division and had arrived in the tenth area on December 19, 1918. While in the Argonne there had been a considerable amount of diarrhea among the members of the command but no cases of typhoid fever. The absence of typhoid in the other batteries of the regiment and in the other units of the division, together with the interval that elapsed after leaving the Argonne before the appearance of the first case, seemed to render it improbable that the infection had been brought from there.

CIVILIAN POPULATION.

Battery E was billeted in Rosoy, a small French town of 400 to 500 inhabitants. The sanitary conditions of the town were fair and the billets as good as the average. According to information obtained from the French civilian physician there had been an epidemic of typhoid fever in this town ten years previously. This epidemic comprised about sixty cases; sixteen of the patients died and were buried on the hillside overlooking the town. The assurance was given that there had been no typhoid in the vicinity for at least two years but this information was later negatived by the discovery by Captain Crawford, during the first week in February, of a case of clinical typhoid fever in a young French girl, at whose home a cook and two other men from Battery E were billeted. The members of the kitchen force were accustomed to congregate frequently at this billet. A specimen of feces from this French girl was sent to the laboratory at Camp Hospital No. 10 and an organism isolated that, in its serological reactions, resembled the *Bacillus paratyphosus* B from which it was concluded that we were dealing with two disease entities that had no immediate relation to each other. More detailed study of this organism with different batches of diagnostic sera resulted in its identification as the *Bacillus typhosus*. The sugar reactions were confirmatory for typhoid rather than paratyphoid. None of the men billeted at the home of this French girl contracted typhoid. The onset of her illness, so far as could be determined, occurred about January 20th, which lead us to the conclusion that she was not the cause of the epidemic but more probably contracted the infection from the same source that the soldiers did or by contact.

FOOD.

All of the food was prepared at the same kitchen and consisted of issue rations with the exception of milk which was purchased locally and presumably boiled before use, although this was not confirmed to the satisfaction of the division sanitary inspector. Many of the men admitted that they had drunk unboiled milk after their arrival in the area. The cooks had been permanent but there had been a shifting kitchen police. French civilians assisted in handling the food when it was transferred from the ration truck to the kitchen. The meals were served from a low field range and it was customary to remove the covers of the food containers and stand them against the wall of an adjacent stone building while mess was served. The ease with which mud could be spattered upon these covers as the mess line passed and thence get into the food rendered this a dangerous procedure that was immediately remedied. Fruits and other edibles were on sale at the civilian stores in the neighborhood and probably some food from these sources was consumed by the soldiers. Green vegetables were not available at the market at this season of the year. Beer and wines, all of which were said to be grossly diluted with water, were on sale at several places. Members of the kitchen force admitted having purchased eggs and chickens

from outside sources for their own consumption. Orders were issued strictly prohibiting the purchase or consumption of food, wine, or beer from civilian sources.

KITCHEN AND LATRINE.

The kitchen was located but a short distance, fifty feet, from the battery latrine. Owing to the fact that soldiers, when not continually under surveillance, become negligent in their personal habits as to the use of latrines and the care of their hands after visiting the latrine this situation had in it an undesirable element of danger and consequently the kitchen was removed to another locality. This made more remote the possibility of fecal matter being tracked from the latrine to the neighborhood of the low field range where it could be easily spattered into the food.

WATER SUPPLY.

The town was supplied with water from two sources, both of which were brought in pipes from springs located some distance from the village. Although the bacteriological examinations of samples from both sources did not show either to be badly contaminated they had been labeled as non-potable and the men had been cautioned against using any but chlorinated water. Previous to the outbreak of typhoid the water had been chlorinated in the Lyster bags after they had been filled from the water carts. Men were observed to fill their canteens directly from the water carts, hence it was ordered that thereafter the chlorination should be done before the removal of any water from the carts. A cook was observed to dip water from the cart and then place the dipper on the muddy ground. This was remedied by having the dipper hung at all times on the water cart. A demonstration of the method employed for chlorination showed it to be satisfactory.

The Lyster bags, which were the only source of chlorinated water, were located at the geographical centre of the town and it was suspected that men billeted in the more remote sections used water from some of the more conveniently situated hydrants. This was confirmed by personal interviews with the men in the hospital. Although they appreciated that the raw water was unfit for consumption they nevertheless used it many times in preference to the chlorinated water. Two men admitted that they habitually drank water from street hydrants or pumps in their billets. Two others depended almost entirely upon beer which, they stated, was grossly diluted with water. Three men used water from a hydrant for cleansing their teeth.

Within fifty feet from the kitchen was a well, the water from which had been exclusively used for kitchen purposes from December 19, 1918, to January 1, 1919, at which time it became dry. A few days later water reappeared in this well and it was again used until the cooks noticed that it had a disagreeable odor. This was called to the attention of the battery commander about January 7th and from that date he prohibited its use. The proximity of this well to the latrine and the odor of the water furnish ample proof of fecal contamination.

It does not require any great imagination to recognize the possibility of a carrier, either soldier or civilian, having deposited the infecting bacilli in the latrine. This leads one strongly to the presumption that this was the source of the epidemic. Although examinations of the water from this well were negative for typhoid bacilli it was heavily contaminated with colon bacilli, which is again strong presumptive evidence of its guilt. Guards were stationed at all water points and strict orders were issued against the use of any but chlorinated water.

TYPHOID INOCULATION.

All members of the command had been inoculated against typhoid and paratyphoid A and B from six to sixteen months previously. Two men gave histories of illness in infancy during which they were confined to bed for several weeks but in all probability they had not had typhoid. Aside from these two men there were none who had had typhoid fever, therefore it was quite certain that we did not have a chronic carrier to deal with. The two men referred to were kept under observation for a month at Camp Hospital No. 10 but repeated examinations of gastric and duodenal contents and feces were negative.

CARRIER EXAMINATIONS.

On February 10, 1919, a systematic examination of the feces of every member of Battery E for organisms of the typhoid dysentery group was commenced. A single examination was made upon every man and, with the exception of twenty-six men, a second examination was made of the whole battery. This was deemed necessary as in the early examinations, made for the purpose of selecting a permanent kitchen force, two were negative on the first and positive on the second examination, the interval being one week. Three hundred and six feces examinations were made for the purpose of detecting carriers and, in addition to this, the actual typhoid cases as well as every member of Battery E, admitted to Camp Hospital No. 10 for any treatment, had from two to ten feces examinations. A total of 390 such examinations were made on members of this battery. As a result three men were found with typhoid bacilli in their feces and were sent to the hospital as carriers. In one of them the condition was later diagnosed as mild typhoid fever. The other two were kept under observation for over a month but subsequent feces examinations at intervals of from three to five days were negative. Before release from the hospital both of these men had seven consecutive negative laboratory reports.

INCIDENCE.

A study of the sick book, together with personal interviews with all of the men who had been sick during the month of January, revealed some interesting information. It became apparent immediately that we were dealing with three distinct groups of cases as indicated by the dates of onset. (Table 1.) The first case was hospitalized on January 16th, nine days after he had first reported as sick call (January 7th). This date, therefore, was taken to be the time of the onset of his first symp-

toms and consequently the beginning of the epidemic.

TABLE I.

Showing group incidence as determined by dates of onset.
GROUP I.

Identification Case Number.	Date of Onset.	Day of Admission.	Confirmatory Diagnosis.	Febriile Period.	
1 1918581	Jan. 7	9	15	26	Death 26
2 1356770	Jan. 12	4	24	29	Death 29
3 2228981	Jan. 14	3	16	38	Death 30
4 404010	Jan. 16	12	24	29	Death 29
5 1357379	Jan. 17	3	18	25	Death 25
6 2234957	Jan. 17	11	29	38	Recovery

SUSPECTED CLINICAL CASES					
21 2233966	Feb. 22	2	0	7	Recovery
22	Feb. 25	2	0	4	Recovery

The interval between the onset of the first and last case in Group I was thirteen days and the intervals between the onset and admission to the hospital varied from three to twelve days. The high mortality of this group suggests two things: a massive infection and a relation between mortality and delayed hospitalization. We believe that both factors were concerned in this instance. We feel quite certain that the well water was the source of the massive infection. It had been used, with the exception of a few days when the well went dry, from December 19th to January 7th, at which time the odor became so objectionable that it was reported to the battery commander and at this same time the first man, who was later diagnosed as having typhoid fever, reported at sick call. In view of the interval of thirteen days between the onset of symptoms in the first and last case in Group I, it is not improbable that the seven men were infected at different times. Statements from the men in the hospital substantiated this view. Some admitted that they had, at different times, washed their mess kits in this well water and that they had drunk it. On at least one occasion it was reported that the cooks had used water from this well to dilute the coffee. Two of the men in Group I, No. 2 and No. 5, were kitchen police.

The onset of the first case in Group II was twenty days after the first and seven days after the last in Group I. The interval between the first and last cases in Group II was only four days. It is our opinion that this group resulted from carrier or contact transmission. The two kitchen police in the first group could easily have been the source of infection for the second group. In addition to this nearly all of the kitchen force lived together in a room just in the rear of the kitchen. There was a member of the kitchen force in the

second group (No. 14). Two other men in Group II lived together and one man from Group II occupied a room with a man in Group III.

The four cases in Group III originated within a period of three days, February 7th, 8th, and 9th, and the intervals between the first case in Group III and the first and last cases in Group II were eleven and seven days respectively.

In the third wave the kitchen force was not spared, No. 15 being a cook. Directly upon the confirmation of the first typhoid fever case among the kitchen personnel (No. 2 positive feces February 5th) the entire kitchen force was reorganized, but on February 9th and 10th, two men from the new kitchen force (No. 19 and No. 20) were found to have typhoid bacilli in their feces and were sent to the hospital for observation. Neither of these men had positive fecal findings after the first examination and they were recorded as carriers. In the sense that they harbored typhoid bacilli in their intestinal tracts without being ill with the disease they were unquestionably carriers but they were not chronic carriers. On the other hand we consider these as examples of the failure to develop the disease because of the immunity established by inoculation, natural immunity, the ingestion of a limited amount of infectious material, or other similar factors. One of these so-called carriers, on at least four occasions had a slight fever without any other symptoms, and we are not convinced but that it would have been more accurate to classify him as a mild case of typhoid fever.

It was anticipated that a fourth group might present itself but such was not the case so far as could be determined. Two cases were regarded with suspicion and carefully observed (No. 21 and No. 22), but it was not possible to establish a diagnosis of typhoid fever in either instance. Although the agglutinin content of their sera was high and one (No. 22) had a positive complement fixation with typhoid antigen, these findings had a limited significance because both men were inoculated with French triple typhoid lipovaccine on January 31, 1919.

After the recognition of the first cases as typhoid fever a careful watch was kept of the temperature of each member of the battery and notes were made of the symptoms complained of by those reporting at sick call. The following were the complaints in the order of their frequency: Headache, eight; weakness or malaise, eight; anorexia, seven; fever, six; generalized pains, six; constipation, five; chills, one, and diarrhea, one.

Further study of the sick book revealed the fact that at the time that the typhoid cases were taken sick, there was a coincident increase in the total sick of this organization. Chart I illustrates this graphically. This suggests that some of these men may have had mild attacks of typhoid fever, perhaps modified by their previous inoculations, the symptoms not having been considered severe enough to cause them to be hospitalized.

Although there may be a reasonable doubt as to the source of this epidemic we believe that the evidence points strongly to the well as the primary

source of infection. The two most probable methods of transmission were: food contamination and contact. Members of the kitchen force might have been passing off typhoid bacilli for days without detection had it not been for the routine daily record of temperatures. By this means four men were discovered in the beginning of the disease that otherwise would have not been hospitalized until several days later. A circumstance that militated against the early discovery of any of the cases from subjective complaints was the fact that it was generally known that the division was scheduled for early return to the United States and for fear of being left behind in a hospital, the men would not report at sick call unless they were very ill.

CASES.

The following cases are briefly related in order to emphasize some features of clinical interest:

CASE I.—(11) Private Battery E, 321 F. A. Admitted February 1, 1919, complaining of headache, chilly sensations, pains in back and legs, vomiting

at sick call and said that he felt feverish and had experienced some abdominal discomfort. The examination by the battalion surgeon revealed no cause and he received symptomatic treatment. His name appeared on the sick book again on February 3rd and 5th but no record was made of his complaints. He did not report sick again but on February 8th he was discovered with a temperature of 99.2° F. On the following morning it was normal but in the afternoon was 100°. On February 10th and 11th there was no fever. On February 12th he was sent by his battalion surgeon to the regimental dental surgeon for an opinion regarding the presence of pyorrhea alveolaris sufficient to account for the intermittent fever. On February 14th, his temperature suddenly rose to 102° and on the following day he was sent to the hospital. On admission he complained only of slight malaise and poor appetite. The spleen was palpable. On the third, fourth and twelfth days there was abdominal pain, sharp and severe on the twelfth day. Four days after admission a crop of

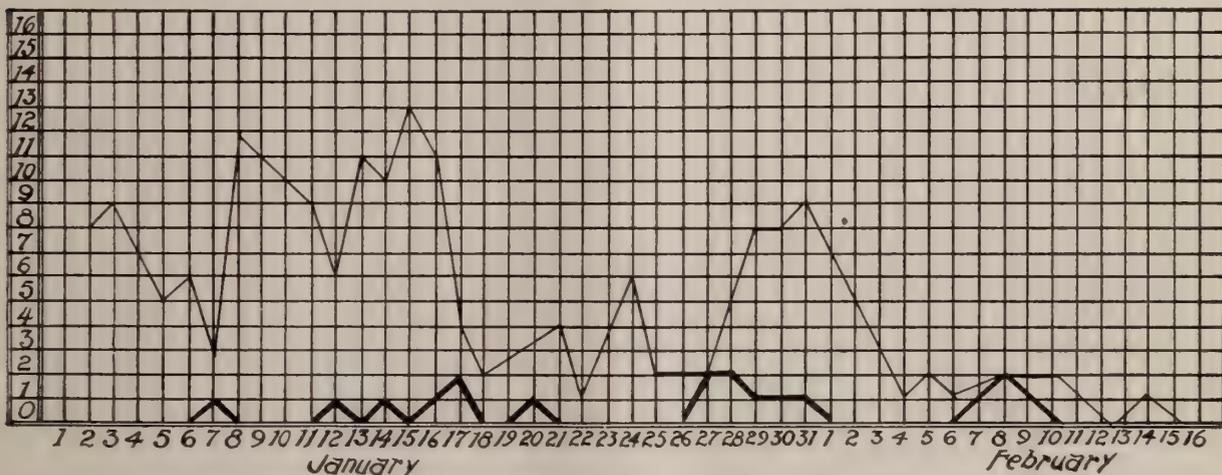

CHART I.—Showing the increase in the number of sick in Battery E, 321st Field Artillery, coincident with the onset of the group of typhoid fever cases. Light line represents total sick for the organization exclusive of typhoid fever cases; heavy line represents the typhoid fever cases.

and nose bleed. Onset January 28, 1919. The diagnosis of influenza was made. There were no objective symptoms of typhoid fever but on the thirteenth day the Bacillus typhosus was isolated from the feces. The temperature was between 102° and 103° F. for the first two days after admission, then 99° to 101° F. for fourteen days when it dropped by lysis to normal. The pulse averaged 80 and the respiration 20. There was no malaise. On the eighteenth day abdominal pain was complained of. No rose spots were noted at any time but on the eighteenth day the spleen was palpable. No blood culture was made. The diagnosis was based on a positive feces, a positive typhoid complement fixation, and a rise in the agglutination titre of the serum for typhoid bacilli. Inoculated with U. S. triple typhoid vaccine July 20, 1918. Febrile period twenty days.

CASE II.—(12) Corporal Battery E, 321 F. A. Admitted February 15, 1919, complaining of nothing but slight malaise and poor appetite. Onset January 29, 1919, at which time the patient reported

rose spots appeared. On the fifth day there was vomiting. The blood and feces were positive on the day after admission. The urine was culturally negative but gave a positive diazo reaction. The typhoid complement fixation was positive and the agglutination titre of the serum high. Both of these serological findings, however, would have been insufficient for a positive laboratory diagnosis in the absence of the positive bacteriological results as the patient had been inoculated with French triple typhoid lipovaccine on January 31, 1919. The temperature averaged 101° to 104°, the pulse 90 to 100 and the respiration 24. On the twelfth day there was sharp, severe abdominal pain with some abdominal rigidity and tenderness. The temperature dropped from 104° to normal, the pulse became rapid and thready, 134 a minute, and the respiration went up to 50. On the thirteenth day after admission the patient died as the result of perforation. The probable period of illness was thirty days, hospitalization being affected on the seventeenth day.

CASE III.—(14) Private Battery E 321 F. A. Admitted February 3, 1919, complaining of headache, constipation and poor appetite. Onset January 31, 1919, and attributed to exposure after a long railroad journey. The patient had been a permanent member of the kitchen police. Constipation was present for the first three days, on the fourth day some abdominal pain was complained of and on the fifth day there was diarrhea. A crop of rose spots appeared seven days after admission and the spleen was palpable on the twelfth day. On the eighteenth day signs of bronchopneumonia were noted. The temperature ranged from 99° to 101°, the pulse from 70 to 80, and the respiration from 18 to 20. Blood, feces and urine cultures were negative. There was a positive typhoid complement fixation and a moderate rise in the agglutination titre of the serum but the significance of these findings was relatively slight because of inoculation on January 31, 1919, with French triple typhoid lipovaccine. The febrile period was thirty-four days ending by lysis. The diagnosis was based on clinical observations but not confirmed by the laboratory.

(To be concluded.)

THE ADMINISTRATION OF DIGITALIS.*

By T. STUART HART, M. D.,
New York,

Visiting Physician to the Presbyterian Hospital.

Digitalis is a real drug. It is worth thinking about, worth talking about and worth using properly. Digitalis will relieve suffering. It will make efficient and prolong the activity of many a damaged heart; often it actually saves life. Also, because it is a real drug it has its dangers. Many a man with a diseased heart does not need it. In a considerable number its administration is distinctly detrimental. I have seen more than one case in which I am quite sure it actually shortened life.

I shall not spend time in discussing at length the indications and contraindications for the administration of digitalis. There are certain groups of cardiac cases in which its use is positively indicated; there are others in which it is just as certainly contraindicated, and there is a very large group in which, in the present stage of our knowledge, it is impossible to make a dogmatic statement, and our only recourse is to try digitalis in effective doses under close observation and watch for its effects. It seems to me that one of the promising fields for study for the individual members and for groups in this Association of Cardiac Clinics, composed of men who are every day seeing so many patients suffering from disordered circulation of all types, would be to study the effect of digitalis on these large groups in which our knowledge is so inadequate, to tabulate the results obtained with all the evidence, and attempt to formulate further rules for the use of this drug. We might thus make some advance and a real contribution to our knowledge of this important subject.

It seems to me that there are just two satisfactory methods of administering digitalis, by mouth and intravenously. Personally I never use digitalis subcutaneously. The active glucosides have a very irritating effect on the soft tissues and invariably when given subcutaneously, produce an area of tenderness and redness which may be very sore and cause the patient a great deal of unnecessary discomfort. When I meet one of my physician friends who is using digitalis subcutaneously, I always ask him whether it does not produce this reaction; frequently he will reply that he has found a new preparation which he is now using subcutaneously and which causes no subsequent discomfort. In my experience this means just one thing, he is using an inactive preparation. When a subcutaneous injection of digitalis gives satisfactory results it also produces local irritation, when there is no local irritation I have failed to obtain a physiological effect. The local effect of the subcutaneous administration is in a way the measure of the potency of the particular preparation. We have a number of preparations which are suitable and convenient for intravenous use, the method is simple, it is the quickest and surest way to obtain physiological results and it causes no local irritation. It is obvious that comparatively few patients are in such an urgent condition that the intravenous route is necessary or advisable; most of our digitalis will be given by mouth.

At the risk of stating what today should be obvious to every physician I want to speak a word in regard to the dose of digitalis. It must be given in quantities sufficient to produce physiological effects. It is distressing to me to see how frequently today one meets physicians of large experience and who are in most respects skillful practitioners, who seem to have no conception of the amount of digitalis which should be administered. They tell you that they have tried digitalis and can get no satisfactory results. On inquiry one often finds that they are administering an inadequate quantity of a good preparation or that they are giving considerable quantities of a preparation which has little real activity. It is often extremely difficult to get physicians to give digitalis in effective quantities and to persuade patients who need it to take it continuously. There are all sorts of traditions in regard to digitalis which seem to die hard. For example, I am frequently told by patients and physicians too that digitalis may be all right while the patient is in bed or sitting in a chair, but they fear disaster if he takes it when walking about. I need not comment on this point of view. Another much dreaded attribute of digitalis is that it unduly raises blood pressure. In some cases with broken compensation the effect of the administration of digitalis is certainly to raise blood pressure. One sees this frequently in cases of auricular fibrillation with low pressure, and in certain cases of hypertension with hearts unable to maintain the pressure which is adequate for the individual needs of the patient, in both of these groups the blood pressure rises as the patient improves. I believe that the favorable results are obtained in these patients by a direct

*Read before the Association of Cardiac Clinics May 11, 1920.

action of the digitalis on the heart muscle and not by a contraction of the peripheral blood vessels. In hypertension without decompensation I have repeatedly administered full doses of digitalis without perceptibly affecting the blood pressure.

One of the most difficult notions to combat is the idea that even the smallest doses of digitalis produce nausea. I believe there is an occasional patient who has an idiosyncrasy to digitalis in whom the vomiting centre is exceedingly sensitive to the drug. These are so rarely seen and so inconsiderable in number that they need scarcely be considered, and yet it sometimes seems to me that nurses and physicians vie with one another in their efforts to impress upon the patient that nausea is one of the early toxic symptoms of digitalis, then when a patient has nausea from the force of suggestion or from some other cause bearing no relation to the administration of the drug, the physician at once orders it discontinued or more often the patient refuses to take it. A patient in whose mind this idea has been thoroughly implanted is sometimes extremely difficult to convince that the digitalis which he regards as his enemy is really his best friend. I very rarely see nausea which is caused by too much digitalis. Far more frequent is it to meet with nausea due to chronic passive congestion of the digestive viscera which the proper administration of digitalis will entirely abolish.

Through the careful studies of Eggleston and others we are now able to calculate approximately the total amount of a digitalis preparation of known strength which it will be necessary to administer to obtain complete cardiac digitalization. Such a calculation permits us to produce complete digitalization much more rapidly than before these formulæ had been worked out. The method advocated by Eggleston is to give at once half of the amount calculated as necessary to produce complete digitalization, six hours later there is given an amount equal to half of the initial dose and at two subsequent six hour intervals a dose half of the second dose. By this plan of administration full effects can be obtained in a majority of instances in from twelve to thirty-six hours.

I have found that when digitalis is administered in these amounts one may not infrequently exceed the dose desired and to say the least may make a considerable number of his patients quite uncomfortable. There is rarely the necessity of thus hastening the production of full effects, and except in the exceptional case I feel that the slower method of administration is much to be preferred. If the Eggleston method is to be used certain precautions must be borne in mind. In calculating the dose due allowance must be made for fluid in the subcutaneous tissues. One must be sure that the patient has not been recently taking digitalis, and to quote Eggleston's own words, "the use of such large doses . . . is not a safe procedure unless the patient can be under nearly constant observation and unless the effects of the treatment can be graphically recorded at frequent intervals."

After a heart is thoroughly digitalized and one has found out just the amount of a given prepara-

tion which is necessary to keep it under proper control, intervals of administration are of very slight importance, if a man needs twenty minims of a certain tincture of digitalis each twenty-four hours it makes no difference, except as a matter of convenience, whether he gets a single dose of twenty minims a day or ten doses of two minims each. There is one factor in the administration of fluid preparations which, while seemingly trivial, is of considerable practical importance, and that is the exact measurement of the dose. On account of the inaccuracy of the medicine dropper patients should invariably be instructed to use a minim glass, even thus administered a considerable variation may occur, and for this reason I feel that the solid standardized preparations put up in tablets or in capsules permit of a more precise dose. The uneven or jerky administration is to be avoided as far as possible; one can most plainly see the undesirable effects of such a procedure in cases of auricular fibrillation where the heart rate is a fair indicator of the degree of digitalization. The drug is commenced with doses of considerable size, the heart rate begins to fall, and after a few days perhaps reaches a rate of sixty, then digitalis is stopped; none is given for a few days and the rate rises to one hundred; then considerable doses are again given and the rate again drops to sixty and the drug is again discontinued. A better way is to allow the rate to reach sixty, then discontinue the drug for twenty-four hours, and begin again with a small daily dose. If it appears that this dose is insufficient to hold the heart at the desired rate the daily dose is slightly increased until we find the exact dose which keeps the heart at its most efficient level; by this method the heart is much better controlled and a great deal of time is saved.

It is well known that in a large number of cardiac conditions we have no such simple guide to the degree of digitalization as is furnished by the heart rate in auricular fibrillation. It is true that such evidence is furnished by the electrocardiograph, but few of us have the opportunity to follow the routine of our cases by this method. It would, therefore, be greatly to our advantage if we were able to use preparations which were carefully standardized so that when we had given a definite amount of one of these preparations we would be morally sure that we had secured effective digitalization.

It appears to me that it would be a very valuable function for the Association of Cardiac Clinics to assume the oversight of the standardization of preparations of digitalis, and I would like to present this thought for your consideration. This could be accomplished by appointing a committee from among the many distinguished members of the association who could, in the first place, formulate standards and later could supervise the examination of preparations on the market much in the same manner that the Milk Commission of the County Medical Society supervises the milk supply. I should like to see marked authoritatively on every bottle containing digitalis the amount in cubic centimetres or grams to the kilo of body weight which should effect complete digitalization.

The aggregate amount of digitalis used by the members of the association must be very great. I think we should soon find that a number of manufacturers would be willing to submit their digitalis preparations to a committee of this association for standardization and would gladly defray the expense of the necessary biological tests for the sake of a suitable endorsement of their products by this association.

160 WEST FIFTY-NINTH STREET.

HYPERTENSION AND ARTERIAL FIBROSIS.

A Preliminary Report.

By C. T. HOOD, M. D.,

Chicago,

Consulting Physician, Cook County Hospital.

There are several reasons for this preliminary report. First, there still remain some unsolved problems, if the hypothesis is to be proved beyond dispute, and it is with the hope that others who are interested in research work will take up this problem, and under better conditions and surroundings complete the findings. Second, clinical evidence, to be of value, in hypertension and arterial fibrosis, must extend over years of time, and the writer trusts that many of his colleagues will thoroughly test the clinical facts related in this paper, and report their results. Third, at the present time, the profession has practically nothing to offer to individuals suffering from hypertension and arterial fibrosis. Fourth, and most important, the clinical results warrant this preliminary report. The details of the experimental work covering now more than five years will be reported at another time.

Perhaps it may seem to the reader that the subject is too broad and covers too much ground, to be considered at one time, but I believe that the stereotyped methods of considering hypertension and arterial fibrosis, each as an entity, is responsible for much of the present poor conception of these conditions, and the present uncertainty of their treatment.

Hypertension and arterial fibrosis are no respecter of persons. They are found in the rich, the poor, the middle class and in the alcoholic; and yet, many old bums whose bodies have been pickled in alcohol almost from boyhood, have neither of them. One man, whose business requires intense mental attention, has both. In another person, under the same conditions, they never develop. Many of the women of the street go free, while in the woman of the home, under the most favorable conditions possible, they develop. One man is habitually constipated and has been all his life, and never presents one positive finding. Another succumbs to them. In other words, so far as we know, we have no definite data as to the etiology of hypertension and arterial fibrosis. Therefore, if he who causes two blades of grass to grow where only one grew can be called a philanthropist, then if we can throw but a passing shadow across the path of this condition, which is taking a greater death toll than

any other disease, not excluding tuberculosis and pneumonia, if we can but hold the light, while some ray penetrates these obscure conditions, we will have done all we hope to do.

In presenting this paper to the profession, we are well aware that we are laying ourselves open to severe criticism, but thirty-five years of active, intensive study and practice have made us immune to criticism, and knowing that we have obtained results, and that others are obtaining results, working along the same lines, prompts us to present the results of these years of intensive study to the profession. In a way the hypothesis to be presented is not new to the profession, yet, the working out of the pathology is. With the exception of the cancer problem, hypertension and arterial fibrosis are two of the greatest unsolved medical problems of the day.

We must ask the reader's indulgence, while we recapitulate some well known facts which are necessary, in order that we may understand the subject under consideration. I believe that there are five types of hypertension:

PHYSIOLOGICAL HYPERTENSION.

In this type, the individual in whom it is found is from sixty to seventy-five years of age. The systolic pressure is 170 to 190, or even 200, with some increase in the diastolic pressure above the normal. The left ventricle is enlarged to some extent, and the aortic second sound somewhat snappy, the urine, while of comparatively low gravity and may at times contain a trace or a considerable quantity of albumin and a few casts, yet, the specific gravity is not fixed, and the night urine is of small volume. In this type of hypertension, the increase in the systolic pressure is due to the wrinkling of the skin, the contraction of the liver, kidneys and spleen, the result of age. This contraction necessarily obliterates an extensive amount of the capillaries. Therefore, if the circulatory balance is to be maintained, and the increased capillary resistance overcome, hypertension must result. This increased capillary resistance is of gradual onset. For some time, years perhaps, the left ventricle is able to maintain the increased pressure necessary to keep up a normal circulation, but by degrees, the back-pressure from the capillaries causes some thickening of the arterial walls, not a true arterial fibrosis, but sufficient thickening to enable the left ventricle to maintain the required hypertension. In this type of cases, the individual presents none or but few of the clinical symptoms of arterial fibrosis. They are able to go about their life, and while not performing a full day's work, are capable of doing from a half to two thirds of a day's work, and as a rule, are rested in the morning. They rarely die of heart failure, but as a rule, from some acute infection, to which they are more susceptible, owing to their lowered resistance.

We wish it to be understood that we are not considering true atheroma, for true atheroma is a much more rare condition than was formerly supposed, and than the laity understand when they speak of hardening of the arteries, but in true atheroma, the hypertension which is present is a necessary physiological process to maintain a normal circulation.

HYPERTENSION IN THE YOUNG.

The second type of hypertension is that type found in comparatively young people, from thirty-five to forty-five years of age. The systolic pressure is from 160 to 190, with some increase in the diastolic pressure, the left ventricular impulse, while somewhat increased in its muscular action, has not, as yet, hypertrophied, the urine is increased in amount. It may contain casts or even a plain trace of albumin, but the specific gravity is good, and the night urine, if there is any at all, is small in amount. The secretion of urea may be somewhat below the normal, but the secretion of chlorides is low.

ARTERIAL FIBROSIS.

The third type of hypertension is due to true arterial fibrosis, and is not due to a physiological process, not due to atheroma, and not the result of chronic nephritis or hyperthyroidism, but the condition begins by an increased resistance in the capillaries, that ultimately results in left ventricular hypertrophy and arterial fibrosis. The pathological condition found in this type we shall consider later. These individuals are from thirty-five to fifty-five, or may even be sixty years of age. The systolic pressure is from 175 upward, with a marked increase in the diastolic pressure.

CHRONIC NEPHRITIS.

The fourth type of hypertension is the result of chronic nephritis. Here, the hypertension is due to the increased resistance in the kidney. The left ventricle hypertrophies to meet this increased resistance, and the back pressure from the kidney results in actual arterial fibrosis, with more hypertrophy of the left ventricle, dilatation and roughening of the aortic arch, and a systolic murmur at the base, a snappy aortic second sound. If the left ventricular hypertrophy becomes extensive, or if from nutritional changes, the left ventricular walls stretch the mitral opening, a mitral systolic murmur will be found. The urinary findings are those of a chronic nephritis, or, more properly, a chronic interstitial nephritis. They are a low fixed specific gravity, a trace of albumin up to one per cent., casts, both hyaline granular and sometimes epithelial. If the chronic nephritis is the result of an acute and subacute glomerular nephritis, fatty casts or fatty globules will be found. The volume of the night urine is equal to or greater than the day urine. The urea is low, as well as the chlorides.

HYPERTHYROIDISM.

The fifth type of hypertension is due to hyperthyroidism, which is never extensive, and never causes death, and is due to the thyrotoxicosis, which produces a spasm of the arterial walls, but never true arterial fibrosis.

In order that we may have an intelligent conception of the subject, we must understand the factors concerned in the production of normal blood pressure, and how these factors may be influenced. We believe that we are absolutely correct, when we say that it is the heart muscle which maintains the normal systolic blood pressure, and that it is the resistance of the coats of the ar-

teries, supplemented by the capillary resistance, that produces the diastolic blood pressure. The factors then concerned in the production of normal blood pressure are, first, the contraction of the heart; second, the volume of blood in the body; third, the resistance offered by the coats of the arteries; fourth, the capillary resistance.

That the contraction of the heart muscle is the first and most important factor in the production of the systolic blood pressure is selfevident. That the volume of blood plays an important part in the ability of the heart muscle to maintain the systolic blood pressure is easily understood. Much has been written, regarding the velocity of the blood stream, in maintaining the systolic blood pressure. The velocity of the blood stream depends upon three factors; first, the size of the stream of blood, which is governed by the size of the arteries; second, the contraction of the muscular coats of the arteries, and, third, the force of the contraction of the heart muscle. With these facts in mind, I am unable to see how the velocity of the blood stream can present any factors in the production of blood pressure not already considered.

The resistance offered by the muscular coats of the arteries must influence the contraction of the left ventricle, for if the contraction of the left ventricle is to empty its contents into the aorta, it must first overcome the weight of the volume of blood in the aorta, and the resistance offered by the muscular coats of the aorta, and the resistance of the blood stream ahead of the aorta. But why is it necessary that in the normal person, the heart muscle must overcome a resistance equal to from 120 to 140 mm. of mercury? Surely it is not to overcome the weight of blood in the aorta and the resistance in the muscular coats of the aorta. No, the resistance offered by the blood in the aorta and the coats of the aorta is due to the back pressure of the blood stream ahead of the aorta. To what is this back pressure due? First, to capillary resistance; second, to the coats of the arteries. As is well known, the function of the muscular coats of the arteries is to change the interrupted flow of blood in the arteries into a continuous flow in the capillaries. In other words, that the flow of blood may be maintained in the capillaries in a normal manner, namely, a continuous stream, constant pressure must be maintained upon the blood stream. Capillary resistance, then, is the real reason for the normal diastolic blood pressure, and the diastolic pressure is the reason for the systolic pressure.

What practical deductions can we derive from these facts? First, any condition that increases or decreases the force of the contraction of the heart muscle will raise or lower the systolic blood pressure. Second, any increase or decrease in the volume of blood will raise or decrease the blood pressure, both systolic and diastolic. Third, any condition which will increase or decrease the size of the arteries will raise or lower the systolic blood pressure. Fourth, any condition which will increase or decrease the velocity of the flow of blood through the capillaries, or, in other words, raise or decrease the capillary resistance, will increase or decrease the

diastolic blood pressure, and thus increase or lower the systolic blood pressure. Many experiments have been carried on to prove these statements, but I believe them to be correct. Clinical examples illustrating these facts are common.

When, from any cause, the heart muscle degenerates or dilates, the systolic blood pressure falls, as does also the diastolic pressure, but the diastolic pressure, does not fall to the same degree that the systolic does. When hypertrophy of the left ventricle occurs, independently of aortic valve disease, the systolic blood pressure is decreased, as in hemorrhage the systolic blood pressure falls, and it may be raised by transfusion, especially the intravenous saline transfusion. If the capillary walls suddenly relax, the systolic blood pressure falls. Such a condition we have when a patient faints, and such a condition exists to a large extent in what is called shock, following the long continued administration of an anesthetic, while the contraction of the capillaries, as in a chill of the surface of the body, the systolic blood pressure will be raised. If a chronic nephritis exists, and the capillary resistance in the kidney is raised, the systolic blood pressure must be raised, in order that kidney function may be carried on. If the heart muscle fails, the kidney function fails or ceases in proportion as the systolic pressure falls.

From these facts, we conclude, first, that capillary resistance is responsible for the diastolic blood pressure; second, that the diastolic blood pressure, or the capillary resistance is the reason for the systolic blood pressure; third, that the heart muscle is responsible for the systolic pressure.

With these facts in mind, let us see if we can deduce a probable hypothesis for hypertension and arterial fibrosis. Considerable time has been given to the part the vasomotor nerves play in the production of hypertension and arterial fibrosis. I do not believe that the vasomotor nerves play any part whatever in the production of permanent hypertension or arterial fibrosis. If this fact is kept distinctly in mind, namely, that the reserve power of the heart or that heart power which is employed when effort is made, this reserve power of the heart is capable of wonderful variations, and as we know, it is the contraction of the heart muscle which produces the systolic blood pressure. Then, when we recall how varied the force of the heart muscle is, under exertion, we must know that the systolic pressure would vary to a great extent, if the calibre of the arteries remained the same, but the vasomotor nerves regulate the size of the arteries to meet the force of the heart muscle. This we believe to be the function of the vasoconstrictor and vasodilator nerves. In other words, the vasomotor nerves are the governors upon circulation, and by their action upon the coats of the arteries maintain the circulatory equilibrium. But physiology teaches us that nerve force cannot be continually applied; therefore, the vasomotor nerves cannot be a factor in the production of permanent hypertension or arterial fibrosis.

What, then, will produce permanent hypertension and arterial fibrosis?

We have already spoken of physiological hypertension, due to contraction of the capillaries, the result of old age. We know that it is on account of the capillary resistance that a systolic pressure is necessary, but what causes the capillary resistance? First, the resistance offered by the splitting up of the arterioles into extensive and exceedingly small vessels; second, the pressure of the body fluids upon the capillaries.

The first proposition is self-evident; the second requires some explanation. We know that the human body contains eighty per cent. fluid, and that this fluid state is absolutely necessary for life. We also know that hydraulic pressure is equal in all directions; therefore, the pressure of the body fluids is exerted as much upon the walls of the capillaries as it is upon the body tissue. If this is true, and we believe that it is, then, the fluid pressure of the body is responsible, entirely or in most part, for the capillary resistance, and any variation in the fluid pressure of the body will influence the capillary resistance. If the capillary resistance is raised, by reason of an increase in the body fluids, the blood stream is held back in the arterioles, backed up from the arterioles into the large arteries. Finally, the pressure is exerted upon the aorta, and by increasing the resistance in the aorta, the left ventricle must increase its force to overcome this aortic resistance. In other words, while the vasomotor nerves may be able to accommodate the size of the arteries to meet the increased resistance in the capillaries, if this increased capillary resistance be continued beyond the physiological time for vasomotor activity, the back pressure is referred to the heart muscle, and hypertrophy of the left ventricle results. If the capillary resistance is continued over years, the left ventricle hypertrophies, and so long as it can maintain the circulatory equilibrium with the arteries at a normal size, this is all the changes required. But if the capillary resistance continues, and the left ventricle finds itself unable to maintain the circulatory equilibrium, then, the coats of the arteries, which have already felt the strain of the increased systolic blood pressure, become fibrosed from necessity, in order to decrease the size of the arteries, and thus assist the heart muscle in maintaining the systolic pressure. And it is such pathological changes that we find at the postmortem table. We find hypertrophy and dilatation of the heart, with fibrosis and dilatation of the aortic arch.

Remember, we are not considering true atheroma with infiltration of the arterial walls, but the much more common condition of arterial fibrosis. Again, we may find arterial fibrosis extending along the large arteries, and sometimes, but rarely, in the smaller arteries. But you ask if the small arterioles are the first to feel the back pressure from the increased capillary resistance, why do we not have arterial fibrosis present more frequently in the smaller arteries? For a purely physiological reason. It is the law of nature that when increased work is required of any part of the body, so long as that part can obtain sufficient blood supply it will increase its working power sufficient to meet the requirement.

The back pressure in the individual arteriole is small, but the aggregate back pressure in many arterioles and small arteries is great, and the full force of the back pressure is exerted upon the aorta and the left ventricle. Thus, we have hypertrophy of the heart, first of the left ventricle, and so long as the left ventricle can hypertrophy to meet the increased resistance, the rest of the heart enlarges but little, but when the left ventricle begins to dilate and the mitral ring is stretched, and the blood begins to be pumped back into the lungs, then, the right ventricle hypertrophies to lend its assistance to the left ventricle, in maintaining the circulatory equilibrium. Ultimately, if the capillary resistance continues, the coronary arteries will fail to supply the heart muscle with sufficient nutrition, or the coronaries may be fibrosed, and the heart muscle will dilate with resulting passive congestion.

SUMMARY.

Increased tissue fluid pressure causes, first, increased capillary resistance; second, hypertrophy of the heart; third, fibrosis of the arteries.

Therefore, the practical application of these facts is, what can and does increase the body fluid pressure in the capillaries? Without, at this time, detailing the experiments which have convinced us of this hypothesis, we believe that it is the presence of sodium chloride in the tissue that brings about this condition. That salt will hold back the body fluids has been abundantly proved, and the clinical results obtained from this fact can be proved by anyone.

Sodium chloride is used in the human body for two and possibly three purposes. First, it is from the sodium chloride that the hydrochloric acid of the gastric juice is made. Of this we have abundant proof. Second, sodium chloride probably plays some part, although this is questionable, in the alkalinity of the blood stream. Third, sodium chloride holds back or retains the fluids in the tissues of the body. It is plain that if the body fluids contain an abnormal amount of sodium chloride for the individual, the intratissue fluid pressure is increased, capillary resistance is raised, and ultimately we have hypertrophy of the heart, with arterial fibrosis.

I am convinced of the truth of these statements. When we remember that the human body requires from thirty to sixty grains of sodium chloride in twenty-four hours for perfect health, and then recall how much sodium chloride is as a rule consumed by the ordinary individual in twenty-four hours, it is not hard to see how capillary resistance is increased. But it is not necessary that the individual be an excessive salt eater. The question is, To what extent is the sodium chloride eliminated from the body? Sodium chloride is eliminated from the body, aside from that used in the manufacture of hydrochloric acid for the gastric juice, first, by the skin and tears; second, by the lungs, to a very small extent; and third and principally, by the kidneys.

Now for the clinical application of these facts. In the first type of hypertension, the physiological type, it must be kept distinctly in mind that these individuals who have a physiological hypertension re-

quire an increased systolic pressure, in order to maintain a circulatory equilibrium. Many of these persons die of some acute infection, owing to their lowered resistance, but if they do not die from the acute infection, they die from heart failure, and they all have a secondary anemia to a greater or less degree. By putting these people upon a salt poor diet, and keeping them on this diet for a time, their excess sodium chloride becomes filtered out. This relieves the kidney of the work of eliminating the chlorides, and permits the elimination of more nitrogen and urea, thus making it possible to allow these people a more liberal protein diet, but keeping them upon a salt poor diet also lowers the systolic pressure, and to some extent the diastolic pressure, to the normal for the individual.

In the second type of hypertension, the pseudo fibrosis, if the individual is comparatively young, from thirty-five to forty-five years of age, the most of them are overweight. They have been good feeders, and have drunk a large amount of liquid, and strange as it may seem, by far the greater number of them have eaten an excess of salt. The urine may show a normal amount of chlorides, for it must be remembered that the blood stream can hold only so much sodium chloride; therefore, the kidney rarely eliminates an excessive amount of chlorides, although this may occur for a short time, but in these cases, even with their excessive liquid drinking, the volume of urine is but little above the normal. Placing these persons upon a salt free diet for a few weeks or two or three months, with a restricted diet in amount, will work wonders. They will do better to dispense with tea, coffee, and tobacco, but they may use these in moderate amounts. By the withdrawal of the salt from their diet, they will at once cut practically all the meats out of their diet, as they will have no taste for unsalted meats for some time, and no salt meats are permitted. The amount of liquids they require is reduced to the minimum, but the volume of the urine will be increased, in some instances enormously increased for a time. They will lose weight for a few weeks, at a rapid rate, then more slowly. By degrees, the volume of urine becomes normal, the gravity is usually above the normal, the systolic pressure will drop rapidly, and if the diastolic pressure has been increased, it will also come down. The dyspnea upon exertion will disappear, the sleep will become better, and they will get up in the morning refreshed.

In the third type, the true arterial fibrosis, the results are not so marked, but the kidney efficiency will be increased, the systolic pressure will be reduced as well as the diastolic pressure. The elimination of the amount of nitrogen and urea will be increased. The aortic second sound will lose some of its snap, and the general condition of the patient will be much improved.

In the fourth type of hypertension, that due to chronic nephritis, not so much can be accomplished, although it is perfectly wonderful what the salt free diet will do for these patients, if it is persevered in for months, and they are permitted to take a well balanced diet. For it must be distinctly borne in mind that besides the uremic symptoms, the most

important symptoms are those due to heart failure and the coexisting secondary anemia. The heart must be closely watched, and given what assistance it requires.

In the fifth type of hypertension, that accompanying exophthalmic goitre, we have had some excellent results by putting these people upon a salt poor diet, the use of the ice bag over the thyroid, the hydrobromate of quinine, and some heart assistants, as sparteine or strophanthus. The sweating quickly subsides and the kidney function is increased, although the diarrhea ceases.

As has been said, the hypothesis we present is in many ways not new to the profession, and we make no assertion that a salt poor or a salt free diet will cure true arterial fibrosis or chronic nephritis, for we know full well that when fibrous changes have once taken place in the arterial walls, these changes will continue for the life of the individual, but we are assured, after more than five years of observation in a goodly number of cases, that such a diet, so far as we can find out, apparently stops the further extension of the fibrous changes, and the individual, if he continues to take only the necessary amount of sodium chloride, may live out his days. We know that in chronic nephritis, where actual pathological changes have occurred, nothing can replace the kidney structure, but by withdrawing the salt from the diet of these individuals for months, and then permitting them only ten to fifteen grains a day, relieves the kidney of much work, permits a much richer protein diet, and thus prolongs the patient's life.

REMEDIES TO ASSIST IN THE ELIMINATION OF THE CHLORIDES.

This is one of the unsolved problems. So far, we have found but one drug, potassium nitrate, which in any way increases the elimination of the chlorides, and this drug is effective in not more than seventy-five per cent. of the cases. Large doses of potassium nitrate increases the volume of the urine, but not the twenty-four hour output of the chlorides, while smaller doses of the drug, as five grains to the ounce, and fifteen drops in a half glass of water, three times a day, will not increase the volume of urine, but will increase the amount of chlorides up to the normal, and maintain this until the individual is filtered of his excess chlorides. In chronic nephritis, potassium nitrate is of little avail, except in the true arteriosclerotic nephritis. In chronic nephritis, other than the arteriosclerotic type, when the urine is of a low fixed specific gravity, with the kidney function from five to fifteen per cent., the administration of eserine, one fortieth of a grain three times a day will increase the chloride elimination for several weeks, then the chlorides will fall to almost nothing, and the nitrogen and urea elimination will increase, often to a marked extent. The question of nephritis of the acute type and what part sodium chloride plays in making it possible for secondary changes to occur is an exceedingly interesting subject, and one fraught with great possibilities.

I believe that it is now considered by the profession that the iodides or iodine has no place in

the treatment of hypertension or arterial fibrosis, that they have no influence whatever upon the course of the disease, that the nitrates, while of service in temporarily reducing the hypertension, to relieve the anginal attacks, are of service, but so far as influencing the course of the disease or producing any permanent results, they are not productive of good.

The salt poor and salt free diet have been used for some years by many clinicians, in the treatment of chronic nephritis, but salt free diet has never, so far as we know, been pushed to the point of the removal of the surplus sodium chloride from the body, and keeping the tissue sodium chloride content at the physiological amount. Herein lie the possibilities.

ENDOCRINOLOGY.

There has been considerable discussion recently regarding the part that the internal secretions play in the production of hypertension and arterial fibrosis. We know some facts regarding the functions of the internal secretions.

The thyroid may cause some increase in the systolic blood pressure, as we find in many cases of exophthalmic goitre, but in other cases of exophthalmic goitre there is a low systolic blood pressure. Simple goitres which become toxic are more likely to increase the systolic pressure. So far as I have observed, and the observation has been fairly extensive, overacting thyroids may increase the systolic pressure, but do not increase the diastolic pressure.

The administration of adrenalin will raise the systolic pressure for a short time, and the lack of suprarenal secretion in the circulation will result in a low systolic pressure. We know, from the ability of adrenalin to control capillary hemorrhage, that it causes contraction of the capillary walls; hence, when there is a lack of adrenalin in the circulation, the capillary walls are relaxed beyond normal. That the secretion of the adrenalins have something to do with maintaining a normal capillary calibre is selfevident, but so far as our knowledge goes, it has nothing to do with the production of hypertension or arterial fibrosis.

In the few cases of Addison's disease that I have had the privilege of studying and observing some facts were common to all. First, the chlorides were below normal in the urine. Second, without exception, individuals suffering from Addison's disease were light salt eaters. We, therefore, are led to conclude that internal secretions do not in any way alter our hypothesis; namely, that sodium chloride holds back the tissue fluids; that an increase in the sodium chloride content of the tissue fluids increases capillary resistance; that increased capillary resistance requires an increased systolic pressure; that an increased systolic pressure demands extra effort on the part of the left ventricle, which may result in hypertrophy of the left ventricle or even hypertrophy of the entire heart, and that arterial fibrosis is an effort on the part of Nature to assist the heart muscle in maintaining the required systolic pressure.

2959 WASHINGTON BOULEVARD.

A CASE OF UNILATERAL CHOKED DISC.

BY FREDERICK KRAUSS, M. D.,
Philadelphia,

Eye Surgeon to the Hospital of the Protestant Episcopal Church.

CASE.—N. A., aged ten, came to the outpatient department of the Episcopal Hospital on April 28, 1919, with the history of increasing blindness in the right eye, following an attack of intense pain over the right forehead accompanied by a scaly rash over both sides of the face. He had had no ocular treatment except glasses at the Wills Eye Hospital two years before.

Upon examination, the right eye was absolutely blind to strong light stimulus. The pupil was inactive to light, but reacted consensually with the fellow eye. The right eye was slightly divergent and perhaps a shade more prominent, but the muscle movements of both eyes were normal. The tension was normal. Ophthalmoscopically the right eye showed a choked disc with apex best seen with plus 6 D the periphery of retina with no lens. The disc was intensely swollen, the vessels were completely hidden appearing again on the retina, with many hemorrhages along the course of the vessels. The left eye had normal vision and practically normal eyeground, the nerve being too grey for his age. The Wassermann, Von Pirquet test and urine were found negative. The x ray examination showed a normal pituitary and normal nasal sinuses. The nasal examination was negative. The general medical examination by Dr. Hooker was negative.

He was then placed on increasing doses of iodide of potassium. There was a gradual decrease of the edema beginning in the periphery of the retina, until the nerve alone appeared swollen, with evidences of chorioidal changes appearing on the temporal and lower sides of the disc.

The vessels were first visible in the periphery with outlines of the disc appearing about two months after the beginning of the treatment. For the vision there was light perception about two weeks after treatment was inaugurated, gradually increasing to fingers counted in five weeks and 20/100 in two months. At the present time his vision is 15/70 plus. His fields of vision are contracted, uniformly

is a semitransparent membrane, which may be a remnant of the hyaloid or more likely exudate resulting from the intense inflammation. The vessels are of good size. The chorioid is disturbed with partial absorption of pigment for a distance of nearly a disc diameter to the temporal and lower sides of the disc. There are no indications of previous hem-

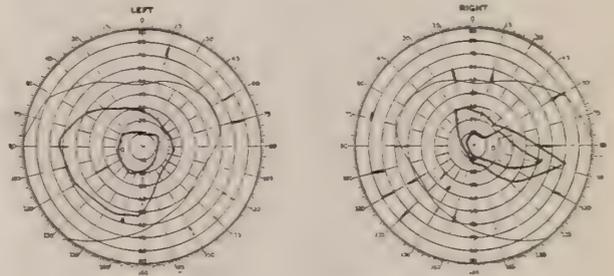

FIG. 2.—Perimeter charts of N. A., January 14, 1920; O. D., LXX—

orrhages. The disc of the left eye, seems too grey— but no gross changes are marked.

The patient has always held his head at an angle. Upon close fixation the right eye tends to turn out. When the fixing hand is carried to the left, the right eye turns inward and upward. (Inferior oblique). When fixing above the horizontal meridian the right eye turns upward and outward. (Superior oblique.) The excessive action of the oblique muscles is probably due to a central cause, following the convulsive seizures.

In the further study of this case we have the following history: His father and mother are well. He has an older sister and a younger brother. Previous to patient's birth, the mother had had two miscarriages.

The patient had convulsions up to his sixth year and especially with the oncoming of the following infectious diseases, measles, chicken pox and pneumonia. The patient has been apparently healthy until three weeks before his appearance in our clinic when he had intense headaches, not relieved by aspirin tablets given him by his mother.

The eyesight was bad immediately with the headaches, but gradually became worse, until he had no vision. In establishing the etiological factor in this case, the miscarriages of the mother above noted are suggestive. The patient showed much improvement under potassium iodide taking forty-five grains three times daily without general symptoms, thus demonstrating the so-called therapeutic test for syphilis. The Wassermann test was negative. This in itself does not prove the absence of syphilis, though I am constrained to believe that a positive Wassermann is proof of its presence. Though marked neuroretinitis was present only in the right eye, an involvement of the left eye is seen in the accompanying fields, which show the left field considerably affected, indicating an optic atrophy. The specific character of the inflammation is also suggested by the improvement possible after severe involvement of the optic nerve (shown in the choked disc).

The retinal vessels instead of being contracted as one ought to expect, were nearly normal in size in the cases examined.

1701 CHESTNUT STREET.

in the left eye and greatly narrowed in the right eye, except to the temporal side.

The ophthalmic appearance of the right eye is as follows: Media clear, disc is oval—90°, quite pale in tint. Running directly across the nerve at axis 105°

SHIFTING AS AN AID TO VISION.

BY W. H. BATES, M. D.,
New York.

When the eye regards a letter with normal vision either at a near point or at a distance, the letters appear to pulsate, or move in various directions, from side to side, up and down, or obliquely. When it looks from one letter to another on the Snellen test card, or from one side of a letter to another, not only the letters, but the whole line of letters and the whole card, appear to move from side to side. This apparent movement is due to the shifting of the eye and is always in a direction contrary to its movement. If one looks at the top of a letter, the letter is below the line of vision, and, therefore, appears to move downward. If one looks at the bottom, the letter is above the line of vision and appears to move upward. If one looks to the left of the letter, it is to the right of the line of vision and appears to move to the right. If one looks to the right, it is to the left of the line of vision and appears to move to the left. Persons with normal vision are rarely conscious of this illusion, and may have difficulty in demonstrating it; but in every case that has come under my observation the patients have always, in a longer or shorter time, become able to do so. When the sight is imperfect the letters may remain stationary, or even move in the same direction as the eye.

It is impossible for the eye to fix a point longer than a fraction of a second. If it tries to do so, it begins to strain and the vision is lowered. This can readily be demonstrated by trying to hold one part of a letter for an appreciable length of time. No matter how good the sight, it will begin to blur, or even disappear, very quickly, and sometimes the effort to hold it will produce pain. In the case of a few exceptional people a point may appear to be held for a considerable length of time; the subjects themselves may think that they are holding it; but this is only because the eye shifts unconsciously, the movements being so rapid that objects seem to be seen all alike simultaneously, just as the parts of a moving picture appear to be seen as one.

The shifting of the eye with normal vision is usually not conspicuous, but by direct examination with the ophthalmoscope, it can always be demonstrated. If one eye is examined with this instrument while the other is regarding a small area straight ahead, the eye being examined, which follows the movements of the other, is seen to move in various directions, from side to side, up and down, in an orbit which is usually variable. If the vision is normal, these movements are extremely rapid and unaccompanied by any appearance of effort. The shifting of the eye with imperfect sight, on the contrary, is slower, its excursions are wider and the movements are jerky and made with apparent effort.

It can also be demonstrated that the eye is capable of shifting with a rapidity which the ophthalmoscope cannot measure. The normal eye can read fourteen letters on the bottom line of a Snellen test card, at a distance of ten or fifteen feet, in a dim

light, so rapidly that they seem to be seen all at once. Yet it can be demonstrated that in order to recognize the letters under these conditions it is necessary to make about four shifts to each one. At the near point, even though one part of the letter is seen best, the rest may be seen well enough to be recognized; but at the distance, in a dim light, it is impossible to recognize the letters unless one shifts from the top to the bottom and from side to side. One must also shift from one letter to another, making about seventy shifts in a fraction of a second. A line of small letters on the Snellen test card may be less than a foot long by a quarter of an inch wide, and if it requires seventy shifts to a fraction of a second to see it apparently all at once, it must require many thousands to see an area of the size of the screen of a moving picture, with all its detail of people, animals, houses, or trees, and to see sixteen such areas to a second, as is done in viewing moving pictures, must require a rapidity of shifting that can scarcely be realized. Yet it is admitted that the present rate of taking and projecting moving pictures is too slow. The results would be more satisfactory, authorities say, if the rate were raised to twenty, twenty-two, or twenty-four a second.

The human eye and mind are not only capable of this rapidity of action, but it is only when the eye is able to shift thus rapidly that the eye and mind are at rest and the efficiency of both at their maximum. It is true that every motion of the eye produces an error of refraction; but when the movement is short this is very slight, and usually the shifts are so rapid that the error does not last long enough to be detected by the retinoscope, its existence being demonstrable only by reducing the rapidity of the movements to less than four or five a second. Hence, when the eye shifts normally no error of refraction is manifest. The more rapid the unconscious shifting of the eye the better the vision, but if one tries to be conscious of a too rapid shift a strain will be produced.

Perfect sight is impossible without continual shifting, and such shifting is a striking illustration of the mental control necessary for normal vision. It requires perfect mental control to think of thousands of things in a fraction of a second, and each point of fixation has to be thought of separately, because it is impossible to think of two things, or two parts of one thing, perfectly at the same time. The eye with imperfect sight tries to accomplish the impossible by looking fixedly at one point for an appreciable length of time, that is, by staring. When it looks at a strange letter, and does not see it, it keeps on looking at it, in an effort to see it better. Such efforts always fail, and are an important factor in the production of imperfect sight.

One of the best methods of improving the sight, therefore, is to imitate consciously the unconscious shifting of normal vision, and to realize the apparent motion produced by shifting. Whether one has imperfect or normal sight, conscious shifting and swinging are a great help and advantage to the eye; for not only may imperfect sight be improved in this way, but normal sight may also be improved.

The eye with normal sight never attempts to hold a point more than a fraction of a second, and when it shifts it always sees the previous point of fixation worse (1). When it ceases to shift rapidly, and fails to see the point shifted from worse, the sight ceases to be normal and the swing is either prevented or lengthened; occasionally it is reversed. These facts are the keynote of the treatment by shifting.

In order to see the previous point of fixation worse, the eye with imperfect sight has to look farther away from it than does the eye with normal sight. If it shifts only a quarter of an inch, for instance, it may see the previous point of fixation as well or better than before; and instead of being rested by such a shift, its strain will be increased, there will be no swing and the vision will be lowered. At a couple of inches it may be able to let go of the first point; and if neither point is held more than a fraction of a second, it will be rested by such a shift, and the illusion of swinging may be produced. The shorter the shift, the greater the benefit; but even a very long shift—as much as three feet or more—is a help to those who cannot accomplish a shorter one. When the patient is capable of a short shift, on the contrary, the long shift lowers the vision. The swing is an evidence that the shifting is being done properly; and when it occurs the vision is always improved. It is possible to shift without improvement, but it is impossible to produce the illusion of a swing without improvement, and when this can be done with a long shift the distance can be gradually reduced till the patient can shift from the top to the bottom of the smallest letter on the Snellen test card, or elsewhere, and maintain the swing. Later he may be able to be conscious of the swinging of the letters without conscious shifting.

No matter how imperfect the sight, it is always possible to shift and produce a swing, so long as the previous point of fixation is seen worse. Even diplopia and polyopia do not prevent swinging with some improvement of vision. Usually the eye with imperfect vision is able to shift from one side of the card to the other, or from a point above the large letter to a point below it, and observe that in the first case the card appears to move from side to side, while in the second the letter and the card appear to move up and down.

In some cases the eyes are under such a strain that no matter how far a patient looks away from a letter he sees it just as well, so long as he sees it at all, as if he were looking directly at it. In these extreme cases of eccentric fixation considerable ingenuity is sometimes required, first to demonstrate to the patient that he does not see best where he is looking, and then to help him to see an object worse when he looks away from it than when he looks directly at it. The use of a strong light as one of the points of fixation, or of two lights five or ten feet apart, has been found helpful. In such cases the patient, when he looks away from the light, is able to see it less bright more readily than he can see a black letter worse when he looks away from it. It then becomes easier for him to do the same thing with the letter. The highest degrees of eccen-

tric fixation occur in the high degrees of myopia, and in these cases, since the sight is best at the near point, the patient is benefitted by practising seeing worse and producing the illusion of a swing at this point. The distance can then be gradually extended until it becomes possible to do the same thing at twenty feet. Usually such patients can begin shifting at the near point with the letters of the Snellen test card, but occasionally it is necessary to use a light, or lights. In hypermetropia, too, the sight is often best at the near point, when the same methods can be used as in myopia.

After resting the eyes by closing, or by covering with the palms of the hands in such a way as to exclude all the light, shifting and swinging are often more successful. By this method of alternately resting the eyes and then shifting persons with very imperfect eyesight have sometimes obtained a temporary or permanent cure in a few weeks.

Shifting may be done slowly or rapidly, according to the state of vision. At the beginning the patient will be likely to strain if he shifts too rapidly, and then the point shifted from will not be seen worse, and there will be no swing. As improvement is made the speed can be increased. It is usually impossible, however, to realize the swing if the shifting is more rapid than two to three times a second.

A mental picture of a letter can be made to swing precisely as can a letter on the test card. For most patients mental swinging is easier at first than visual swinging, and when they become able to swing in this way it becomes easier for them to swing the letters on the test card. By alternating mental with visual swinging and shifting rapid progress is sometimes made. As relaxation becomes more perfect the swing can be shortened, until it becomes possible to conceive and swing a letter of the size of a period in a newspaper. This is easier, when it can be done, than swinging a larger letter, and many patients have derived great benefit from it.

All persons, no matter how great their error of refraction, when they shift and swing successfully, correct their error of refraction partially or completely, as demonstrated by the retinoscope, for at least a short fraction of a second. This time may be so short that the patient is not conscious of improved vision, but it is possible for him to imagine it, and then it becomes easier to maintain the relaxation long enough to become conscious of improved sight. For instance, the patient, after looking away from the card, may look back to the large letter at the top, and for a fraction of a second the error of refraction may be lessened or corrected, as demonstrated by the retinoscope. Yet he may not be conscious of improved vision. By imagining that the C is seen better, however, the moment of relaxation may be sufficiently prolonged to be realized.

When swinging, either mental or visual, is successful, the patient may become conscious of a feeling of relaxation which is manifested as a sensation of universal swinging. This sensation communicates itself to any object of which the patient is conscious. The motion may be imagined in any

part of the body to which attention is directed. It may be communicated to the chair in which the patient is sitting, or to any object in the room, or elsewhere, which is remembered. The building, the city, the whole world, in fact, may appear to be swinging. When the patient becomes conscious of this universal swinging he loses the memory of the object with which it started, but so long as he is able to maintain the movement in a direction contrary to the original movement of the eyes, or the movement imagined by the mind, relaxation is maintained. If the direction is changed, however, strain results. To imagine the universal swing with the eyes closed is easy, and some patients soon become able to do it with the eyes open. Later the feeling of relaxation which accompanies the swing may be realized without consciousness of the latter, just as the letters may swing without consciousness of the fact, but the swing can always be imagined when the patient thinks of it.

Associated with all failures to produce a swing is strain. Some people try to make the letters swing by effort. Such efforts always fail. The eyes and mind do not swing the letters; they swing of themselves. The eye can shift voluntarily. This is a muscular act resulting from a motor impulse. But the swing comes of its own accord when the shifting is normal.

NONLEUCOTOXIC PROPERTIES OF BENZYL BENZOATE.*

BY EDWIN A. HELLER, M. D.,
Philadelphia,

AND EDWARD STEINFELD, M. D.,
Philadelphia.

Through pharmacological studies of the opium alkaloids, Macht was able to separate them into two classes: the pyridin phenanthrene group and the benzyl isoquinolin group, with morphine as the principal representative in the former and papaverin, the typical member of the latter group. He further noted that the alkaloids of the papaverin group were able to effect the relaxation of smooth muscle and were able to antagonize the tonus increasing properties of the morphine group. This relaxing effect was demonstrated to be due to benzyl grouping in their molecules and in the search for similar bodies of a simple and nonnarcotic nature, benzyl benzoate and benzyl acetate were investigated. These were found to produce the same tonus lowering effects and appeared to be eminently safe for clinical use, with the exception that the acetate was irritating when taken by mouth.

Following these investigations, benzyl benzoate has come into widespread use in nearly all conditions indicating the relaxation of smooth muscle. Because of its close chemical derivation from benzol, it has

appeared to us to be of interest and even advisable to investigate any possible analogy to the toxic effects of the latter. Though the untoward manifestations of benzol are varied, we have selected its destructive action on leucocytes as being capable of more accurate determination and comparison with the benzoate. The studies of various observers have shown the leucotoxic effect of benzol and for this reason it was formerly used as a therapeutic agent in leucemia. The problem could not be approached very well from the clinical side, since it was not justifiable to use larger doses than recommended by Macht, and because conditions could not be so thoroughly controlled as in an experimental study using animals. We have therefore used rabbits, which were the animals usually used by investigators upon benzol in the past. Certain precautions were used to ensure accuracy. That is, several preliminary leucocyte counts were made to recognize tendency to variation in the counts, since this variability exists in these animals.

The animals were then given subcutaneous injections of benzyl benzoate in equal parts of olive oil into the loose tissues of the flanks, the preparation used being the full strength benzyl benzoate and not the alcoholic dilution, which will not mix with oil. The doses used varied from one cubic centimetre to two and five tenths cubic centimetres to the kilo of body weight, these being given in one injection, with the exception that one rabbit received four doses of twenty-five hundredths c. c. each. Two rabbits were used as controls to demonstrate the destructive effects of benzol, so that comparisons could be made with the same lot of animals under similar conditions. As can be noted, the doses used were considerably larger in comparison than those used clinically. Leucocyte counts were then made daily until a tendency for the figures to remain constant was noted, and then made every other day. The results are shown in the accompanying table, and as can be noted, doses of one quarter c. c. to the kilo for four days, and doses of one, one and five tenths, two, and two and five tenths c. c. to the kilo apparently had no appreciable effect in lowering the leucocyte count. However, the animals given the largest amounts showed the ill effects of the drug by lethargy, weakness and in one case death was not preceded by leucopenia.

In contrast with these animals, the two control animals receiving benzol in doses of one and five tenths c. c. and two c. c. to the kilo, showed definite evidences of depression of the leucocyte count, which later came back to approximately normal.

For convenience in reading the table, the data concerning the various animals may be summarized as follows:

RABBIT I.—Female, weight 1,200 grams; four injections of twenty-five hundredths c. c. each of benzyl benzoate to the kilo.

RABBIT II.—Male, weight 1,500 grams; one injection of a cubic centimetre of benzyl benzoate to the kilo.

RABBIT III.—Male, weight 1,450 grams; one injection of one and five tenths c. c. of benzyl benzoate to the kilo.

RABBIT IV.—Male, weight 1,630 grams; one injection of 2 c. c. benzyl benzoate to the kilo.

RABBIT V.—Male, weight 1,350 grams; one injection of two and five tenths c. c. benzyl benzoate to the kilo.

*From the Clinical Laboratories of the Jewish Hospital.

RABBIT VI.—Male, weight 1,680 grams; one injection of one and five tenths c. c. benzol to the kilo.

RABBIT VII.—Male, weight 1,340 grams; one injection of 2 c. c. benzol to the kilo.

LEUCOCYTE COUNTS AFTER INJECTION OF BENZYL BENZOATE AND BENZOL.

Days After Injection	Rabbit No.						
	1	2	3	4	5	6	7
Preliminary	9,100	11,200	8,500	12,600	8,100	8,400	7,800
1	9,200	11,400	8,100	12,100	7,400	5,000	6,100
2	8,600	11,100	8,000	13,400	7,800	4,000	4,100
3	8,800	10,900	9,100	12,500	7,000	7,000	4,200

11	dead	8,700	8,100	7,200

Rabbits 6 and 7 received benzol.

CONCLUSIONS.

1. Benzyl benzoate was found to be without toxic effects upon the leucocytes of rabbits.

2. Controls of benzol showed the well known depression of the leucocyte count.

3. A wide margin of safety is present between the therapeutic doses and the toxic doses of benzyl benzoate, based upon observations on rabbits.

LOBAR PNEUMONIA COMPLICATED BY MULTIPLE ARTHRITIS.*

Report of a Case.

By DAVID GREENBERG, M. D.,

New York,

Chief of Medical Clinic and Assistant in Pathology,
Lebanon Hospital.

The occurrence of two or more diseases, especially of the acute febrile type, simultaneously in the same individual, is of interest because of its bearing on diagnosis, prognosis, and treatment. Early during the onset the presence of multiple infections renders a diagnosis difficult or impossible. When a diagnosis is established because of signs and symptoms characteristic of one disease, manifestations of another disease may erroneously be regarded as a complication of the first. Then, when the presence of two distinct entities is recognized, the prognosis becomes more uncertain on account of the complexity of the factors to be taken into consideration. Lastly, should there arise complications, it may be almost impossible to decide which of the diseases is responsible, which often means the difference between surgical intervention and absolute rest.

With the difficulty thus encountered in separating two diseases, and with the justifiable hesitancy one has in diagnosing two diseases when one disease may possibly account for all the symptoms, it is evident what a problem it is to estimate the frequency of such double affections. From the published reports and Board of Health figures one is led to believe them rather uncommon. Yet it is only logical to assume that many double infections are probably overlooked, because when the attention is centered on a particular disease one is likely to overlook the appearance of another, regarding it

as a complication, unless ushered in with violent or characteristic symptoms. This tendency to focus our attention on one problem only perhaps explains the comparative decrease in the incidence of ordinary diseases during the prevalence of an epidemic disease. Many of the ordinary diseases are then overlooked and are regarded as atypical cases of the epidemic disease.

From a theoretical viewpoint one may assume that in the event of two or more infectious organisms together in the same host there is a certain interrelationship, and they have either a deleterious or a beneficial effect on each other. *In vitro*, one species of organisms may have an inhibitory influence on the growth and development of the other. The reverse is true in other instances, when the presence of one organism may help the development of the other, as in the case of an aerobe, which is often necessary to facilitate the development of an anaerobe. Bacteriologists speak of it as symbiosis and enantobiosis or synergism and antagonism. Clinically, while the phenomenon of synergism may be said to be rather common, as in the case of secondary invaders in tuberculosis and streptococcus, in measles the phenomenon of antagonism is rather rare. A critical analysis of cases where double infection occurred would be interesting if such record were available. In the case here reported there seems to have been a shortening of the febrile course by the appearance of polyarthritides during the course of pneumonia.

CASE.—S. C. H., male, born in the United States. His family history was irrelevant. Previous history: He had the ordinary diseases of childhood. His habits were good; denied venereal disease. Three months previously he had had an attack of appendicitis with an abscess, for which he was operated upon at St. Francis Hospital. During his convalescence pneumonia developed (postoperative), and after that he suffered from pain in the right shoulder, which disappeared after about three weeks.

His present illness began on May 7, 1919, with a chill and fever. The patient stated that for two days previous he felt somewhat tired, but he went to work on the morning of the 7th and had to come home in the afternoon because he felt too sick to hold out longer. I saw him late that afternoon, when he had the appearance of a man acutely ill, with eyes and throat congested, face flushed, temperature 105.2°, pulse 130, respiration 20. There were no definite lung signs then except slightly diminished breathing and relative dullness at left base, with a few sibilant râles at right base. The next day there were signs of lobar pneumonia at the left base posteriorly and in the left axilla. The temperature remained at about 104.5°, and pulse about 120. The respiration became more frequent, between 35 and 40. The blood count at that time was 30,000, with eighty polymorphonuclears and twenty lymphocytes. The urine contained a slight amount of albumin, but no casts, pus, or blood. Sputum was blood tinged and later became rusty. A culture of sputum showed the predominating organism to be Type IV.

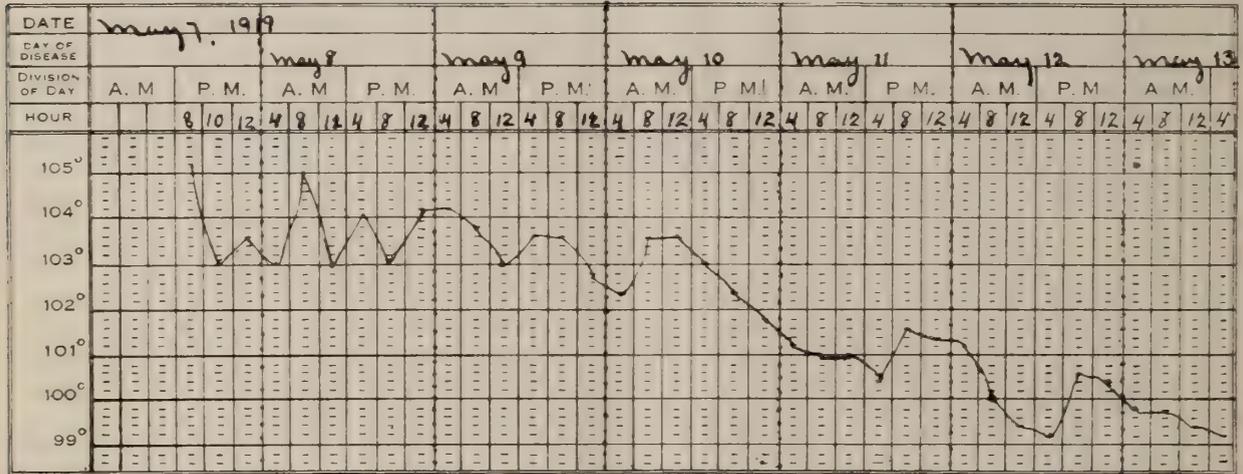

*Read before the Alumni of the Lebanon Hospital, New York, March 2, 1920.

On the third day of illness the patient's condition was very serious. He had signs of extensive involvement of the entire lower and part of upper left lungs, as well as a small patch over right angle of scapula. He was cyanotic and there were some moist râles over both lungs. He was given atropine and digalen intravenously. Toward evening some pain in the left shoulder developed which was thought to be the result of extensive pleuritic involvement.

The following day the patient complained of pain in his left knee, and later in the day, in the right ankle. On examination, the ankle and knee were found to be red, swollen, and tender. About the same time the temperature began to fall, and

kles, both knees, both elbows, the left hip, left shoulder, and left first and right second metacarpophalangeal joints had been involved. During the course there were also present small areas of erythematous patches around these joints. They were thickened and tender and varied in size from one to three cm. The patient eventually recovered completely.

In the case here reported there seems to have been a decided shortening of the usual acute course in lobar pneumonia. A glance at the temperature chart shows a drop in the fever coincident with the appearance of articular symptoms, although there was no change in the physical signs in the lungs at that time. This calls to mind the recent attempts

CHART—Temperature chart of S. C. H.

in twenty-four hours was 100.2°. The left elbow and right shoulder became red and swollen next day. The whole clinical picture was that of an acute polyarthritis of rheumatic origin. There was marked redness, much tenderness and swelling and inability to move the joints, either actively or passively. When the first joints became involved there was a doubt as to whether we were dealing with a pneumococcus arthritis. The blood count, which had gone up then to 48,000, with eighty-three polymorphonuclears, would have been in favor of that assumption. However, the patient looked much better despite his joint involvement. The subsequent manifestations in other joints and the ready response to salicylates eliminated pneumococcus arthritis, which is usually monoarticular, is associated with a septic temperature, and does not respond to salicylates.

The course of the pneumonia was rather unusual. After the temperature became normal the extensive lung signs remained about the same from nine to ten days, when signs of resolution slowly began to appear. At the end of about three weeks the patient still had some dullness over the left base posteriorly.

The joint manifestations ran a clinical course typical of an ordinary attack of acute articular rheumatism. The migratory tendency of the joint involvement was very decided. Within a week after the first appearance of the arthritis both an-

that have been made to shorten the course of certain diseases by the introduction of nonspecific bacteria, such as polyvalent vaccines intravenously. The success with chronic arthritis in the hands of some observers by the intravenous injection of typhoid vaccines received considerable attention four or five years ago, and only last year there were similar attempts made to influence the course of influenza by the injection of streptococci and staphylococci, in order to raise or bring about a leucocytosis. Certainly, some of the favorable results that some observers claim to have obtained by polyvalent vaccines, or sera, and phylacogens, may not be entirely due to a nonspecific protein reaction, but may, in some measure, be due to the phenomenon of symbiosis and enantobiosis. It would be worth while to study this subject from a clinical as well as a bacteriological viewpoint.

1220 GRAND CONCOURSE.

Syphilis and Pregnancy.—William J. Young (*Surgery, Gynecology and Obstetrics*, May, 1920) in a study of syphilis and pregnancy came to the following conclusions: Routine Wassermann examination should be made in obstetrical wards of charity institutions when patients are admitted. It should be just as much the duty of the obstetrician to ascertain evidence or history of lues in his patient as to conduct delivery.

LONDON LETTER

*(From our own correspondent)**Venerable Disease Clinics and Professional Secrecy.—Next Year's Census.—Dinner to Sir George Watkins.*

LONDON, May 22, 1920.

In other chapters the commission dealt with the problems of infant mortality, and conspicuous contributory causes of loss of population as, for example, venereal disease and alcoholism. With respect to the treatment of venereal disease they record their opinion that taking into consideration the gravity of the situation, the Ministry of Health would be justified in calling the attention of the public to the fact that abstinence from promiscuous intercourse is the only thoroughly effective method of preventing the spread of disease, and that it is the urgent duty of every citizen who, in disregard of the claims of morality and citizenship, exposes himself to the risk of infection, to use some method of disinfection either personal or by private medical treatment or by attendance at an early treatment centre at the earliest opportunity. Further, if on later investigation the methods of self-disinfection should prove to be more effectual in preventing the spread of venereal disease than the methods of disinfection at early treatment centres, then the National Birth Rate Commission think that any difficulties of an administrative kind which may now prevent registered chemists from selling such disinfectants should be removed, provided such preparations are only to be sold when accompanied by a notice that they are to be used for disinfection only and are useless for treatment.

The report commented on is an exceedingly valuable one, inasmuch as it discusses with the utmost frankness the two outstanding obstacles to a fruitful birth rate. Also it may be noted the suggestions and findings of the commission apply with almost equal force to America as to this country. Birth restriction is prevalent in all civilized countries, and of course, America is not exempt. The most deplorable feature of the case is that it is a survival of the least fit, or, at any rate, not of the most fit. The class that is most likely to bring forth progeny of the type from which the most desirable citizen is evolved, refuse to have even decent sized families. The inexorable consequence must be that if such a course be continued, the undesirable class will predominate and will swamp the desirable class and will rule the world. This is a very serious situation and one which must be squarely and resolutely faced.

Dr. Addison, the Minister of Health, received at the office of the Ministry on May 6th, last, a deputation from the London and Counties Medical Protection Society, Ltd. The chairman of the London and Counties Protection Society Dr. C. M. Fegen, on behalf of the deputation, urged upon the Minister of Health, the necessity for early legislation to protect the medical officers of venereal disease clinics from being compelled in the witnessbox to violate the established principles of professional secrecy, and to give information of their patients' ailments and of anything else which came to their knowledge in their professional capacity. He said that the

medical officers of venereal clinics were being compelled in the law courts, under penalty of imprisonment for contempt of court, to reveal what their patients had communicated to them, believing that the information would be regarded as absolutely confidential. It was pointed out that the effect of this would be disastrous to the working of the venereal disease clinics. The Minister of Health expressed his complete concurrence with the views of the deputation, and promised to do what he could to promote legislation as suggested by the deputation. He said, moreover, that he felt certain that public opinion would support the maintenance of professional secrecy in connection with venereal disease clinics.

* * *

In 1921 the decennial census of Great Britain is to be taken. Viscount Astor, secretary to the Ministry of Health, has introduced into the House of Lords a bill making the necessary provision for the purpose. Hitherto, it has been necessary to pass a bill on the occasion of each enumeration, but should the present measure become law, special legislation will be dispensed with in future, and the necessary arrangements will be provided for by order in council. Power is also sought to direct the taking of a census every five years. In future enumerations British householders will be required to state the following particulars: 1. Names, sex, age. 2. Occupation, profession, trade or employment. 3. Nationality, birthplace, race, language. 4. Place of abode and character of dwelling. 5. Education. 6. Infirmity or disability. 7. Condition as to marriage, relation to head of family, parentage, issue. 8. Any other matters with respect to which it is desirable to obtain statistical information with a view to ascertaining the social or civil condition of the population. Provision is made for the enumeration to be carried out by the Registrar General under the direction of the Minister of Health, and for the issue of regulations prescribing the procedure to be followed.

* * *

A complimentary dinner to Sir George Watkins, president of the Royal College of Surgeons, and late consulting surgeon to the British Expeditionary Forces, was held in the Hotel Great Central, London, on the evening of May 10th, last. A large company was present, including Sir John Goodwin, Director General of the Army Medical Department; Sir James Porter, late Director General of the Naval Medical Services; Sir John Bland Sutton, vice-president of the Royal College of Surgeons; Sir William Fletcher, representing the Medical Research Council; Sir John MacAlister, for the Royal Society of Medicine; Dr. Alfred Cox, for the British Medical Association and Mr. F. G. Hazzett, for the Conjoint Examination Board of the Royal Colleges. Sir Cuthbert Wallace gave the toast of the evening which was seconded, if such a term is applicable, by no fewer than four persons, Sir John Goodwin, Mr. E. F. White, Sir John Bland Sutton and Sir George Savage, the well known alienist, who in the course of his speech gave a humorous sketch of Bedlam some forty years ago. The dinner was a success from all points of view.

tation through the mail as second class matter.

NEW YORK, SATURDAY, JULY 31, 1920.

SCIENCE AND IMAGINATION.

While it is true that scientific knowledge represents the grasping of hard facts, this by no means signifies that the scientific man should be devoid of imagination or that imagination has no place in the building of science. The discoverer, the pioneer of science, is notoriously a man of imagination or he would not be a discoverer. His is the speculative mind; he theorizes and then sets himself to prove that his theories are right. In his remarkably able and fascinating address a few weeks ago as president of the British Medical Association, that grand old man of medicine, Sir T. Clifford Allbutt, regretted the fact that the schools are teaching too much detail, and that the universities do not stimulate the imagination as in times gone by. The true scientist is born, not made; a person can have an absolutely scientific mind without knowing one science and conversely an individual can have a hopelessly unscientific mind although his brain may be gorged with scientific facts. Accurate knowledge is essential, but the gaining of such knowledge may be carried too far and become narrow specialization, exact knowledge on one subject, but no broad outlook. The human mind does not need monuments of laborious research so much as the play of imagination of the master mind which regards the subject as a whole. Therefore Sir Clifford insisted that science and imagination should go hand in hand and that detail should be the complement of imagination. It is obvious that science cannot make great progress without the aid of imagination. The highest

type of man is the theoretical and contemplative, and he only reaches perfection when these gifts are allied with the genius for bringing them into effect.

The imaginative genius frequently lacks the practical instinct and must rely on the common sense plodder to reduce his theories to utilitarian purposes. But the imaginative man is essential if scientific medicine is to continue to advance, and consequently the warning to the modern schools and universities not to dwell too much on detail but to leave plenty of scope for the exercise of the imagination is altogether justified.

VACATION TIME.

During evolutionary processes man tries to fit into the various niches which are created through his own efforts. At times progress is more rapid in one field than another and it requires great effort to maintain a balance. During all this manipulation the struggle for existence makes itself manifest by the continuous grind to which we are subjected. The physician is especially aware of these factors which he must face. He is required to fit himself into the modern world with its rapidly changing molds, to struggle along in a competitive race to make his living, serve mankind by administering to the sick, making his own adjustments. In this constant striving he is obliged to observe and give back to medicine his own findings and so pay his debt to science. He is obliged to study the findings of other men, making use of them for the benefit of his patients.

Frequently the medical man does not realize in the course of his constant endeavor to alleviate suffering that he owes to himself a period of rest and recuperation. His responsibilities are greater, however, than those of many other workers, for he cannot stop the incidence of disease while he leaves his practice and seeks a retreat from its cares and anxieties. From time to time, however, he should think of the duty he owes to himself. We have found that the ideal condition for the human body is alternate work and rest. This holds also for the mind. Many physicians do more reading during their vacation time than during the rest of the year. Many of them who do not have time for study during the busy months of active practice take the opportunity for study. They review the literature that has accumulated and in the peace and quiet of the country they can assimilate and make use of the material they find. To be

able to cast aside the responsibilities of their everyday tasks and revel in the medical literature constitutes a real vacation for these men. They are refreshed and return to their work with a new vigor. Other physicians, who are able to combine their studies with their practical work, require a change which they find in the more vigorous out of door sports, and the most exciting thing many of them do during their vacation days is to lie on the banks of some quiet stream tending a fishing rod and dreaming of the time they ran away from school to enjoy a similar day's sport.

In any event, the physician is entitled to a vacation. He deserves it and owes it to himself and to his patients. He returns to his work with a new outlook upon life and can give more of himself, for the life of the physician, more than that of any other occupation, consists in giving. But he must keep himself fit, in body and in mind.

THE TREATMENT OF VOMITING IN NURSLINGS.

A problem of almost daily occurrence to be solved by the physician is that of the treatment of vomiting in nursing infants. In the first place regurgitation, where the infant rejects the excess of milk which it has ingested, must not be mistaken for vomiting. This takes place immediately after nursing, the milk rejected being liquid and without any change having occurred. Vomiting arises some time after nursing and the milk is coagulated. In the newly born hematemesis, melena and incoercible vomiting due to pyloric stenosis or from a congenital intolerance for all kinds of milk are encountered. These cases are exceptional, so that the vomiting due to an alimentary cause or to some intrinsic pathological factor alone will be considered. In the former the vomiting is produced either by irregularity in feeding, by overfeeding or underfeeding or something defective in the food. The causes are to be looked for in the hygiene or defective diet of the infant, its general state of health and in a too great richness of butter or casein in the milk. If the child is bottle fed the cause may be bad feeding of the cow furnishing the milk, various changes of the milk occurring during transportation or to uncleanliness of the instruments—bottle and rubber nipple—or an excess of butter or casein.

In a weaned infant the abuse of feculents may lead to the same result, like any other food disproportionate to the age of the child. Various pathological states may produce vomiting. Thus it is in affections of the digestive tract—dyspepsia, enteritis, infantile cholera, appendicitis, intestinal oc-

clusion or invagination, hernia and affections of other systems—meningitis, encephalitis, various infectious states, etc. If the infant is breast fed the feedings should be regulated and given at proper intervals, frequent if there is reason to suppose that the baby is underfed. The health and diet of the nurse must be examined into and an analysis of the milk should always be made when the vomiting persists. Before each feeding a teaspoonful of the nurse's milk should be given to which has been added a pinch of chymosin, pepsin or lab ferment. Maternal milk should not be regarded defective until the sterile milk test has been made. Stop maternal feeding for two days, during which time the nursing is fed on cow's milk properly diluted and sugared; if the vomiting ceases or decreases it is due to the nurse's milk.

If the infant is bottle fed the origin of the milk must be watched, as well as cleanliness of the bottles and nipples. Aerophagy is avoided by holding the bottle so that the neck is always filled with milk during the feeding. After the fourth month begin to concentrate the milk according to the infant's tolerance. Light vegetable broth and maltose bouillon can also be given. Anhydric diet is indicated in vomiting resulting from acute diseases for twelve to twenty-four hours and should it still persist a dry diet may be resorted to for two or three days. If the baby is weaned the feedings must be regulated and the abuse of feculents, meat and fats avoided. Other therapeutic measures such as hot packs over the epigastric region can be applied in appendicitis, while if the vomitus has a butyric odor or if there is a gastrointestinal intoxication, gastric lavage may be done. A teaspoonful of sodium citrate or dilute hydrochloric acid in proper dose can be given before each feeding. Operation is urgently required if the case is one of pyloric stenosis, appendicitis or invagination.

INSOMNIA DUE TO DYSPEPTIC STATES.

Dyspeptic subjects frequently suffer from disagreeable forms of insomnia presenting certain characteristics which individualize them and facilitate their diagnosis. In these forms of insomnia the patients are nervous, overwrought, and in a state of depression quite incompatible with a normal life. In the end a true neuropathic condition exists.

There are three principal varieties of insomnia due to digestive disturbances. In the first and most common form the patient falls asleep easily but is awakened regularly at a certain hour by a gastric paroxysm, accompanied by pain, pyrosis,

and belching, sometimes relieved by a change of position. This pain follows the movements of the patients to a certain extent and becomes localized on the side upon which they lie. It is sufficiently severe to prevent sleep and only subsides toward morning, allowing the patient to fall into a heavy sleep from which he arises in a state of fatigue, without energy, possibly suffering from vertigo, and quite incapable of physical or intellectual effort.

In the second variety of insomnia, the patient always experiences, at about the same hour every night, a feeling of malaise which seems in no way to be due to the stomach. After a period of restlessness, haunted by disagreeable dreams, he awakens, drenched with perspiration, with a rapid pulse, a difficult, anxious respiration, and a sensation of distress and painful weight in the cardiac region. Assuming the sitting posture and belching up considerable gas affords some relief, but the patient is often unable to fall asleep for hours, and as a consequence in the morning he is fagged out and only by the greatest effort is able to leave his bed.

In the third variety the patients are wakeful all night and lose consciousness only during brief periods. The best way to prevent these cases of insomnia, which are frequently encountered in practice and often misunderstood, as well as the nervous states engendered thereby, is to treat the digestive disturbances which are the underlying cause.

COMMERCE AND PSYCHOLOGY.

A few years ago a narrow minded commercial man would have enjoyed an article which recently appeared in a New York paper on the mistakes and failures, even the cruelty, of those doctors who undespairingly wrestle against tuberculosis. "Waste of time; waste of Government funds," his comment. Today he pricks up his ears; psychology can teach him how to get the best value from employees; can save him many a compensation and pension. Here is one of his helpers, a gentleman who puts E. P. R. I. after his name, which simply means he is an employment psychologist in the rubber industry, and the results of his work are an enormous saving to the company. This is explained in the *Journal of Applied Psychology* for March, 1920.

But those who cannot appreciate the ramifications of medical science certainly will not understand the work which is being added yearly to the tired doctors' crowded day. Indirectly, even the general practitioner must be able to meet and discuss cases with a real or partly assumed interest. He must agree with or fight the law court verdict as to mental conditions, and a dual personality case in an employee does not mean a dual fee; perhaps, even none at all.

CANADA'S WORK FOR DISABLED SOLDIERS.

In a splendid pamphlet just published by the Department of Soldiers' Civil Reestablishment, in Ottawa, is described the work that is being done for the disabled soldiers in Canada. From a careful reading of the book it will be seen that this work has been done with energy and thoroughness. No department has been neglected. Careful attention has been given to the physiotherapeutic fields, a branch of therapeutics which has come to the fore during the war, showing that more progress can be made by carefully directed physical methods than by surgery or medicine. In fact, it has grown to be one of the most dependable and most widely used methods of treatment.

The work done has been of a very high order and every effort made to secure comfortable and cheerful surroundings for the men. Many needs have received attention that were neglected in former postwar methods of treatment. Modern dentistry has received the attention it deserves. Workers in this field will read this valuable book with a feeling of great satisfaction.

News Items.

Virginia Medical Meeting.—The Medical Society of Virginia will hold its next meeting October 26th to 29th in Petersburg.

Married.—Dr. Albert Ernest Gallant, of Forest Hills, N. Y., and Mrs. Mary Claire Parsons were married June 14th. They will live in Forest Hills.

Death of Dr. Zander.—Dr. Gustav Zander, the originator of the Zander system of mechanical therapeutics, is dead at Stockholm at the age of eighty-five.

Proposed American Hospital in Philippines.—A campaign to raise funds for the establishment of an American hospital is being conducted by American residents of the Philippines.

Royal College of Surgeons Elects Officers.—Sir Anthony Bowlby has been elected president and Sir Charles A. Ballance and Sir John Bland have been elected vice-presidents of the Royal College of Surgeons.

Italian Congress of Medical Radiology.—A congress under the auspices of the Societe Italiana di Radiologia Medica will be held October 28th to 30th in Rome, under the presidency of Professor Francesco Ghilarducci.

Appointment of Dr. Geiger.—Dr. Jacob Geiger has been appointed director of the pathological laboratories of the New York Diagnostic Clinics and after a survey of the better American laboratories will reorganize the present laboratories of this institution.

Dinner to Dr. Mayo.—A dinner was held in London on Tuesday, July 6th, with the double object of honoring Dr. Charles H. Mayo and of introducing to public notice the movement for founding an American Hospital. The speakers included Lord Reading, Dr. Mayo, Mr. Balfour, Mr. John W. Davis, and Sir Arbuthnot Lane.

Major General Gorgas to Lie in Arlington.—The body of Major General Gorgas, who died recently in London, will be buried in Arlington National Cemetery.

Appropriation to Fight Disease.—An appropriation of \$80,000 has been made to the New York City Health Department by the Board of Estimate for the purpose of preventing the invasion of cholera, bubonic plague, smallpox, and typhus, which are now ravaging sections of Europe.

Iowa Medical Meeting.—The Iowa State Medical Society held its sixty-ninth annual meeting May 12th to 14th in Des Moines. The following officers were elected: President, Dr. Alanson M. Pond, of Dubuque; vice-presidents, Dr. C. P. Howard, of Iowa City; Dr. J. W. Osborn, of Des Moines. The next meeting will be held in Des Moines.

Ontario Medical Meeting.—The Ontario Medical Association at a meeting held the latter part of May elected the following officers: President, Dr. J. H. Mullin, of Hamilton; vice-presidents, Dr. F. J. Farley, of Trenton, and Dr. F. A. Clarkson, of Toronto; secretary, Dr. T. G. Routley, of Toronto; treasurer, Dr. G. Stewart Cameron, of Peterboro.

Medical Society of Northern Virginia and the District of Columbia.—At a meeting held at Alexandria on May 19th this society elected the following officers: President, Dr. George Tully Vaughan, Washington; vice-president, Dr. Arthur Hooe, Washington; recording secretary, Dr. William T. Davis, Washington; corresponding secretary, Dr. Joseph D. Rogers, Washington; treasurer, Dr. Robert S. Lamb, Washington.

Arkansas Medical Society.—The Arkansas State Medical Association met recently in Eureka Springs and elected the following officers: President, Dr. G. A. Warren, of Black Rock; vice-presidents, Dr. Robert H. Huntington, of Eureka Springs; Dr. A. J. Clinton, of Lockesburg, and Dr. Thad Cothorn, of Jonesboro; secretary editor, Dr. William R. Bathurst, of Little Rock (reelected); treasurer, Dr. Henry R. Kirby, of Little Rock. The next meeting will be held in Hot Springs.

Virginia Commission on Medical Education.—The following medical men have been appointed to the Commission on Medical Education in Virginia, the body which has been created to make recommendations leading to the establishment of a single state supported medical school in Virginia: Dr. Beverley R. Tucker, of Richmond; Dr. James H. Dillard, of Charlottesville; Dr. Julian A. Burrus, of Blacksburg; Dr. Stuart McGuire, of Richmond, and Dr. Theodore Hough, University of Virginia.

Massachusetts Central Health Council.—A Central Health Council for the purpose of promoting cooperation between the various health agencies throughout the state has been organized in Massachusetts. In the new organization are represented public health nursing, child welfare, medical and dental groups, tuberculosis, cancer, state and local health officials, the Red Cross, and the American Public Health Association. Dr. Enos H. Bigelow, of Framingham, is president. It is expected that by means of this organization duplication and overlapping of duties may be eliminated.

Police Department Sanitarium.—Plans are under way for the erection of a sanitarium in the Catskills or in the Adirondacks for members of the New York City police department who become ill.

United Hospitals Report.—According to an announcement by a member of the executive committee, the United Hospitals Fund of New York last year provided 2,438,811 hospital days, of which 1,203,728 were free days. Free treatment was given to 698,335 persons.

Sanitary Code Amended to Prevent Anthrax.—The Sanitary Code of New York City has been amended to provide for sterilization of hair used in toilet articles, in order to prevent anthrax. The sterilization must be according to rules laid down by the Board of Health.

Complete Medical Course at Wisconsin University.—The medical course of the University of Wisconsin, heretofore only two years, will be expanded to a complete four year course, by the terms of legislation recently enacted. The teaching of the third year will probably be offered in the fall of 1923 and that of the fourth year in the fall of 1924. A state hospital will also be established at Madison.

United States Civil Service.—The United States Civil Service Commission announces examinations on December 1, 1920, for the positions of bacteriologist at \$130 to \$180 a month, associate bacteriologist at \$90 to \$130 a month, assistant bacteriologist at \$70 to \$90 a month, junior bacteriologist at \$70 a month, and junior bacteriologist (part time) at \$30 to \$50 a month. Announcement is also made of an examination on August 31st for the position of pharmacologist in the Public Health Service, at \$3,000 a year.

Died.

BRANDENBURG.—In New York, N. Y., on Saturday, July 17th, Dr. Charles Wesley Brandenburg, aged sixty-nine years.

CAMPBELL.—In New York, N. Y., on Sunday, July 25th, Dr. Harry E. Campbell, of Pittsburgh, Pa., aged sixty-one years.

COOK.—In West Stockholm, N. Y., on Friday, July 9th, Dr. Martin Dutton Cook, aged eighty years.

EIDENMULLER.—In San Francisco, Cal., on Saturday, July 10th, Dr. William Cooper Eidenmuller, aged sixty-four years.

FLAGG.—In Hyde Park, Vt., on Friday, July 9th, Dr. Rowley Smith Flagg, aged thirty-two years.

KINMOUTH.—In Belmar, N. J., on Wednesday, July 21st, Dr. Hugh S. Kinmouth, aged seventy-three years.

LESTER.—In Seneca Falls, N. Y., on Sunday, July 18th, Dr. Elias Lester, aged eighty-four years.

LONG.—In Haddonfield, N. J., on Wednesday, July 14th, Dr. William Sumner Long, aged sixty-five years.

MCCURDY.—In Bangor, Me., on Thursday, July 8th, Dr. Charles L. McCurdy, aged sixty-six years.

PARKER.—In Willimantic, Conn., on Saturday, July 17th, Dr. Theodore Raymond Parker, aged sixty-four years.

PARSONNET.—In Newark, N. J., on Tuesday, July 20th, Dr. Victor Parsonnet, aged forty-nine years.

SMITH.—In Bridgeport, Conn., on Wednesday, July 14th, Dr. Edwards M. Smith, aged sixty years.

VAN WERT.—In New York, N. Y., on Sunday, July 25th, Dr. John Irving Van Wert, of Patton, Pa., aged fifty-five years.

Book Reviews

FOLKLORE IN THE OLD TESTAMENT.

Folklore in the Old Testament. Studies in Comparative Religion, Legend and Law. By Sir JAMES GEORGE FRAZER, Hon. D. C. L., Oxford; Hon. LL.D., Glasgow; Hon. Litt. D., Durham Fellow of Trinity College, Cambridge. In Three Volumes. London: Macmillan and Company, Limited, 1919. Pp. xxv-569; xxi-569; xviii-566.

"The proper study of mankind is man." Man is no less the proper study of that branch of human interests which pertains to the discovery and the maintenance of the principles upon which his health rests, namely medicine. Sir James G. Frazer has been one of the chief servants in the past in furnishing an extensive background for any branch of study of man's needs, a background whose chief theme has been man and man only. For his works are concerned with gathered material from the records of humanity itself, records engraved in folklore, custom, superstition, religious belief and practice, in the actions and modes of thought discoverable among all races and all conditions of men still to be found upon the face of the earth and in whatever traces of former times.

Psychological medicine at least has come to find such material indispensable in investigation of the reactions, the archaic modes of thought and feeling, the residue of experiences which still linger in the unconscious of each individual. These have left their mark in deeply fixed tendencies which lie in the hidden mental life of man and play an enormous part in determining outer reactions, still influencing man's attempts to deal with the social world in which he lives today. Frazer himself says in the preface to these recent volumes: "The instrument for the detection of savagery under civilization is the comparative method, which, applied to the human mind, enables us to trace man's intellectual and moral evolution, just as, applied to the human body, it enables us to trace his physical evolution from lower forms of animal life. There is, in short, a comparative anatomy of the mind as well as of the body, and it promises to be no less fruitful of far-reaching consequences, not merely speculative but practical, for the future of humanity."

The author has at his command such a vast amount of this material gathered and sorted and compared by him through many years of scholarly work that he can bring to bear an overwhelming force of fact upon any theme of man's development and man's interest which he chooses as his starting point. The title of these volumes suggests at once a pathway into human history where the comparative method must yield rich results and at the same time grant new and deeper appreciation of the introductory topics themselves. These belong to the ancient Hebrew religion, which in its turn is of fundamental interest to all Christendom. From the study of these topics there comes an illumination of still more fundamental psychological facts out of which these larger formulas of religion have sprung. The author's spirit of reverent appreciation of truths and modes of thought and belief which have rendered tremendous service to

humanity, as well as his fearless seeking of the fundamental human psychology underneath, are warrant for the true value of these books. He has moreover a literary style of more than usual grace and beauty which has its basis in a genuine spirit of kindly constructive comparison and criticism, an ability not only to see two sides of a question but to bring these harmoniously into a mutual service in the search for underlying fact. Through all this there runs a bubbling stream of humor which lends to the reader a quicker appreciation of the absurdities and false logic of much of the primitive affective form of thinking and the results to which such thinking leads. At the same time it makes the reader more tolerant, reaching as it does unawares into his unconscious sympathy with the infantile reactions of our ancestors. When we consider the etiological factors our judgments are tempered.

Frazer has taken for the arrangement of his work certain important or certain strangely obscure topics pertaining to the Old Testament religion and then has given himself license to range freely over the face of the earth for similar material. He thus illustrates the fuller meaning of these things as they lie in the origin and development of the Hebrew faith. He shows the inherent value and significance of these factors as they appear different merely in outward form in the religions and customs, the hopes and fears, of men over the wide world and through different times. Thus he also clears up many an obscurity and gives meaning where the original pragmatic value had been covered over through the distortions of reinterpretation and redirection of the underlying significance.

For the literary and the theological critic he has an interesting opening discussion of the twofold record embodied in the Old Testament, the earlier traditional one, the more picturesque, rich in redolent folklore, as Frazer himself describes it, and the later intellectualized version of the same material made by the priestly cult. He discusses the creation and fall of man with the participation of the serpent in the latter, his bringing of the message, the fatal interpretation of which led to death, to all of which rich parallels are found in widely different parts of the earth. The discussion of the mark put upon Cain and the reason for this mark is a significant chapter for the earliest history of legal conceptions and the faint foreshadowings of legal code.

Comparative study leaves the reader with a far different regard for Cain and a very different understanding of his position in early society than the orthodox theological or legal one would afford. Some confusing discrepancies in the narrative are also resolved when we learn that Jehovah was really kindly disposed to Cain, this "first Mr. Smith, for Cain means Smith," as the author considerably tells us. He was probably protected by the mark set upon him from his victim's ghost, not branded with a sign of frightfulness and shame, the former according better with the primitive estimate of a murderer's status in society. Feeling is

altered also in regard to the apparent scheming of Jacob against his older brother when it is learned that there was once a widespread existence of ultimogeniture which preceded the custom of primogeniture known to more recent society. The latter has been so long accepted that the memory of a reverse principle in society has fallen to the level of the distorted tale by which Jacob's character has long been defamed.

Great interest attaches to the comparative study of the legend of the flood. This long chapter is a reprint of the annual Huxley lecture delivered by the author and therefore is especially characterized by the writer's charm of literary production, his gracious handling of opposing views, his delicate humor with which he makes merry with his readers, though never discourteously to the childish thinkers of the past, over their infantile type of thought and narrative which he in such manner more fully reveals. This chapter would form a valuable monograph in itself upon a much investigated, much contested subject and one upon which Frazer's studies yield vast stores of material illustrative of unconscious modes of thought and the content of this deeper mental life. Perhaps still more important in questions of medical psychology, in the light of Freud's investigations in the relations of the individual to the family group, is the extensive chapter dealing with the slow development of social feeling and custom in regard to cousin marriages and the marriage of a wife's sister or of a deceased brother's wife. These subjects are introduced by the pastoral tale of Jacob's wooing of the two sisters, Leah and Rachel, the older necessarily before the younger more desired one. The chapter consists of a long discussion of the gradual alteration of social feeling and custom in regard to these marriages. It is full of illustrative material but falls almost into the category of extremely technical matter, for the details which regulate and belong to these customs among different peoples and at different times, as social feeling and custom pass from one stage to another, would require special time and application for their study. It forms nevertheless a valuable chapter for such reference and in its general revelations throws light upon the problems lying within the present day unconscious "family complex" with its place in social history as well as in individual conflict.

The literary background in which all these collected details of comparative matter are woven together, through the author's ripe scholarship and power as a writer, is never one to tempt to idle self enjoyment. It stimulates to thought and speculation of many sorts. He revives a fading interest in the Old Testament, one which ought not to pass away but one which should grow to a wider and deeper appreciation of its stores of material because of his treatment. Frazer's three volumes deserve a place on the shelves of the library, those shelves which stand closest to the retreat of an idle hour and those most accessible for the busy student. They should form part of the indispensable equipment of the special worker in the mysteries and complexities of the mental disturbances of the men and women of today.

IRISH FOLKLORE.

Visions and Beliefs in the West of Ireland. Collected and Arranged by Lady Gregory. With Two Essays and Notes by W. B. Yeats. In Two Series. Illustrated. New York and London: G. P. Putnam's Sons (The Knickerbocker Press), 1920. Pp. vii-293; iii-343.

Oh, to live in the enchanted land of Ireland, to share the hospitable mood of its people which freely welcomes to their daily life the strange images of the dream world! One can steep oneself in Lady Gregory's volumes until the partitions between this world and some other are fairly dissolved—for the moment, until one again awakes. It is perhaps too bad that most of us on both sides of the Atlantic have been so trained in scientific thought, we have kept ourselves so well afloat in the world of logical sequence, because it seemed useful and workable so to do, that we cannot be satisfied with continual wandering on such uncertain boundaries. Some advanced thinkers have even dug out from the workings of the human mind a single unifying formula, they call it "wish fulfilment," which sets all these strange beings to scampering into the realm of unsubstantiality and accounts for all their strange forms and trickeries. Mr. Yeats in his labored comments has no such simple satisfying explanation. His attempts to explain and to locate these beings, essences, whatever they may be, show a lack of logic which may satisfy a puerile animistic style of thinking but which hardly accords with the simple, logical directness of evolution. Cause as a fundamental background gradually unfolding out of itself has no place for him. Therefore he tells us only that souls, spiritual beings, exist and take any shape they will and appear as and how they will. Yet sometimes they are limited and forced to other, or partly other appearances, a confusion of shapes. Is this evolutionary logic?

Although the Irish know it not they are oftener nearer to the more simple scientific formula than that. "They can do nothing without some live person is looking at them." "It is something in our own eyes makes them big or little." They all but acknowledge the root of wish fulfilment or its distortion. Of the latter the mind permitting a wish to come through from the uncritical unconscious into the light of conscious requirements is easily capable. No wonder, if these visions and beliefs are products of their own minds, that they take familiar shape and form, manifest desires similar to those of their creators. The latter lead a hard existence with an absence or a severe limitation of the joys and beauties they so often ascribe to these beings. It is not a peculiarity of the Irish to be able to dream and express their desires thus even in waking belief in these dreams. "There's no doubt at all but that there's the same sort of things in other countries; but you hear more about them in these parts because the Irish do be more familiar in talking of them." Not only so but they have maintained to an unusual degree a childlike spirit of beauty and delight, as an ambivalence toward their environment. At all events they hold to the kindly and lovely side of these beings and ascribe to even the distorted, ugly forms a desire to do no harm except under provocation. They give testimony frequently in their

own statement of their belief, to which Lady Gregory has adhered throughout, to various phases of mental condition in which deliria and dreams are prominent. There are the periods of being "away," suggestions of epileptic or other fits, and the not inquent "drop too much." Stress of loss of dear ones plays a large part. The two volumes form a rich and charming addition to the study of the products of the vast unconscious world of phantasy which forms the greater part of all of us and to the peculiar power of all, particularly of this race, to project the unconscious material outside the self and there reinterpret it. There is shrewd testimony on the part of some of the harder hearted, more realistic inhabitants, "Walking Coole demesne I am these forty years, days and nights, and never met anything worse than myself." Have we or shall we ever, any of us?

TRAVEL FOR THOSE WHO STAY AT HOME.

White Shadows in the South Seas. By FREDERICK O'BRIEN. With many illustrations from photographs. New York: The Century Company, 1919. Pp. iii-450.

Thirty-seven days' sail from Tahiti lie the Marquesas, those tragic islands of the South Seas where the last members of a race are dying. "Here in these islands," says the author, "the brothers of our long forgotten ancestors have lived and bred since the Stone Age, cut off from the main stream of mankind's development. Here they have kept the childhood customs of our white race, savage and wild, amid their primitive and savage life. Here, three centuries ago, they were discovered by the people of the great world, and rudely encountering a civilization they did not build, they are dying here." There is much of easy, simple living in these islands; there are many "sun-steeped days on white beaches," but there is also much of degradation. A hundred years ago there were 160,000 Marquesans; the number today is estimated by the author at less than 2,100. Tuberculosis and taxes, smallpox and syphilis, leprosy and opium, the cupidity of the trader and the strange gods of the missionary have been brought to the islands by the white men, and the Polynesian is dying under them. As Titihuti, she of the tattooed legs, says: "We will all be gone soon, and the coconut groves of our islands will know us no more. We come, we do not know whence, and we go, we do not know where. Only the sea endures, and it does not remember."

The reader who elects to journey with Mr. O'Brien will be well repaid, for this book is different from most travelers' tales. It is not scenery or customs or atmosphere that the author is trying to reproduce, but the life of which these form a part, and life in the Marquesas is shot through with simplicity and beauty and melancholy. Our white author, with his *Golden Bed* and *The Iron Fingers That Make Words*, was treated by the natives as one of themselves, and in return he has done them the honor of not being sociological about them. Perhaps it is because he lived their life instead of merely observing it, and because he approached them with their own friendliness, that his book is rich in the comprehension which so

few white men feel for others not of their own color.

It is one thing to travel; it is another to recreate far places so perfectly that the reader has the illusion of having been there himself. Mr. O'Brien does this, and even more—he recreates the enchantment that travel has for those imprisoned against their will by the coil of circumstances. This book, written "for those who stay at home yet dream of foreign places," should be read by all those in whom the daily routine has not quite buried the dreams of the romance that lies over the world's rim.

MYSTERY AND MEDICINE.

The Pathway of Adventure. By ROSS TYRRELL. New York: Alfred A. Knopf, 1920. Pp. vii-310.

The individual reader borne breathlessly along this *Borzoi Mystery* highroad on coming to the end will say, "An unlikely story," half ashamed that he had really enjoyed the journey. But, should that man ever be in lazy chat with some dozen companions, he will find that nearly all can tell stories as strange and confirm the daily probability of the improbable. The beguilement of such books as those by Ross Tyrrell lies in the fact that they gratify the love of adventures which every man secretly longs for, and that hope of ultimate justice in that the hero always triumphs in the end over the forces of wrong arrayed against him. As in this story, four villains, armed with deadly weapons, are of no avail against the virtuous hero armed with a broken bladed penknife or a table leg. They may leave him wounded and gagged in a dank cellar or throw him out of a window or crack his skull, but he revives in a manner which should inspire every surgeon who figures in the *Annals of Surgery* with his "unique cases."

Such literature used to be advertised as "railway fiction" for travelers, but it is rather to be recommended in this day for reading in breezy, quiet holiday resorts, where the reader will have a chance of regaining a normal pulse rate after wild adventuring through its pages.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE WHISPERING DEAD. By ALFRED GANACHILLY. New York: Alfred A. Knopf, 1920. Pp. xi-279.

THE HISTORY AND POWER OF MIND. By RICHARD INGALESE. New York: Dodd, Mead & Co., 1920. Pp. xxiv-329.

THE EARTHOMOTOR AND OTHER STORIES. By Dr. C. E. LINTON. Illustrated by MURRAY WADE. Salem, Oregon: Statesman Publishing Co. Pp. xiii-231.

THE REAL CAUSE OF STAMMERING AND ITS PERMANENT CURE. A Treatise on Psychoanalytical Lines. By ALFRED APPELT. Second Edition. London: Methuen & Co., Ltd. Pp. xi-234.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Thirty-first Session, held in Atlantic City, N. J., June 16, 17 and 18, 1919. Edited by OSCAR M. SCHLOSS, M.D., Vol. 31. Pp. xv-270.

Miscellany from Home and Foreign Journals

Coccygodynia.—Charles J. Drueck (*Western Medical Times*, March, 1920) says that coccygodynia is to be thought of in every patient with anal or sacral pain. In every rectal examination the coccyx should be carefully palpated and manipulated to determine any faulty position, undue sensitiveness, abnormal mobility or rigidity, or infiltration of tissue about the region. In mild cases nothing may be found but a tender spot on one or the other surface or at the tip of the coccyx. In other cases dislocation or fracture may be found, or a projecting bony spicule. In severe cases the patient may writhe or scream during the examination. A further examination of all the pelvic organs is necessary in order to exclude disease elsewhere, and sometimes this is impossible without an anesthetic. The prognosis in general is good. In many cases cure is spontaneous, though it may require months, so recent cases should be treated conservatively. Rest and hygiene are indicated until the acute symptoms subside; local medication and bandages are worthless. Sedative drugs and analgesics should not be used for fear of inducing a drug habit. The bowels should be kept open. A hot rectal douche at 105° F. for five minutes twice a day is sedative and relaxing to the tissues. External heat with the therapeutic lamp one hour night and morning is also of much value. Faradism, one pole over the coccyx and the other above the sacrum, or within the rectum, according to the location of the painful spots, is good. The injection of eighty per cent. alcohol into and about the sensory nerves often is satisfactory. The point of maximum tenderness is determined by digital examination. The index finger is retained within the rectum as a guide, a two inch needle is introduced through the skin in the posterior raphe, is carried to this sensitive area, and ten to twenty minims of eighty per cent alcohol is slowly injected. The injections may be repeated in five to seven days. They may be given without anesthesia, but most careful asepsis must be observed. If the suffering continues after a thorough trial of palliative treatment, excision of the coccyx is required.

Experiments on the Eye with Gas Mantles of Different Compositions.—C. E. Ferree and G. Rand (*American Journal of Ophthalmology*, January, 1920) reports experiments made with Welsbach mantles of known size and composition as to the effect of the light they furnish upon the loss of efficiency and discomfort caused by a certain amount of eye work done under such illumination. The conspicuous variables in these experiments were composition of light, a physical variable, and color value, a sensation variable, which are not synonymous and do not always go hand in hand. It is a natural inference that the results obtained were due to differences in the color value of the illuminants used, but it is conceivable that differences in composition of light may affect the power of the eye to sustain clear and comfortable seeing. They may affect the resolving power of the eye; they may exert an immediately deleterious or irritating action

on the delicate structures of the eye; they may have an effect on acuity through the color of the sensation aroused. If one were willing to draw conclusions with regard to composition and color value of light at this stage of the investigation, he would be inclined to say that in case of a given color the power of the eye to sustain clear and comfortable seeing decreases with the saturation of the color; but that independent of saturation some colors affect the eye more than others. A displacement from white toward a dominance of the short wave lengths of the spectrum affects the eye more than a similar displacement toward the long wave lengths. In considering the relative merits of illuminants the comparatively low surface brilliancy of the gas mantle should not be forgotten, it is of practical importance in the problem of providing adequate shading for the eye. In connection with the problem of shading the writers recommend that the 0.75 per cent. ceria mantle, and other mantles of low ceria content, be used with shade so selected that its color effect is corrective of the greenish coloration of the light given by these mantles. The amber shade should exert in some measure such a corrective action on the greenish light of the "standard" mantle.

Tartar Emetic in Ulcus Tropicum.—A. Mei (*Journal of Tropical Medicine and Hygiene*, February 2, 1920) states that tropical ulcer is very prevalent among the natives of Cyrenaica. In most of the cases seen, the *Spirochæta schaudinni* was found in the lesion. The known value of tartar emetic in various protozoal diseases led the author to try it in this affection, with marked success. Even when the drug is merely applied externally, the patient must be kept at perfect rest in bed. The copious secretion from the ulcer is removed with dry sterile gauze. The tartar emetic is applied only in small amount to the surface of the ulcer and beneath its margins, and the lesion then covered with sterile gauze and a light bandage. Applications are made at first twice and then once daily, according to the amount of secretion. The average duration of treatment is one month. Only occasionally, among children and European patients, is there intolerance to the remedy; iodoform is then substituted. Tartar emetic acts strongly on the spirochetes. After two or three days they are reduced to small numbers, in a degenerated condition, whereas the Vincent bacilli and various cocci are still present in large numbers. By the fifteenth day, all Vincent bacilli and spirochetes are gone, and only a few cocci remain. The ulcer improves coincidentally with the diminution and disappearance of the spirochetes, suggesting that these organisms constitute the true etiological agent in ulcus tropicum. In two native boys, intravenous injections of 0.06 grain of tartar emetic were given. Distinct but slow improvement followed, and later local treatment was substituted, with very good results. Treatment by intravenous injections of the remedy may prove useful in cases in which external application gives very severe pain, but is otherwise unnecessary.

Action of Curara on the Output of Epinephrine from the Adrenals.—G. N. Stewart and J. M. Rogoff (*Journal of Pharmacology and Experimental Therapeutics*, December, 1919). found in experiments on cats that curara in doses sufficient to paralyze the skeletal muscles markedly repressed the output of epinephrine from the adrenals. The depression begins promptly, and may be still well marked when the paralysis of the muscles has begun to wear off. No attempt was made to compare exactly the doses of curara required to paralyze the epinephrine secretory fibres and the cardioinhibitory fibres, but a marked diminution in the epinephrine output was observed in samples of blood collected from the adrenals at a time when stimulation of the vagus caused inhibition of the heart. In general, curara should not be employed in experiments on the epinephrine output.

Mitral Stenosis in Soldiers.—T. F. Cotton (*British Medical Journal*, December 27, 1919) reports observations on seventy-five patients with signs of mitral stenosis, and analyzes the histories of fifty of these. Tests with the exercise tolerance of the patients led the writer to conclude that the increase in pulse rate is a useful sign in estimating the exercise tolerance, but it is not of value in distinguishing between early and developed mitral stenosis. The average early mitral stenosis showed better exercise tolerance than the disordered action of the heart, but when the distress after exercise was as great in stenosis as in D. A. H. the pulse rate rose as high after exercise in the one as in the other. It is pointed out that the symptoms of cardiac failure may be observed in patients with no signs of structural disease of the heart and in particular in cases of D. A. H. The suggestion is made that the same cause produces the symptoms in early mitral disease as in D. A. H. Prognosis is discussed and emphasis is placed on the importance of any considerable enlargement as an unfavorable sign.

Pupillary Symptoms in Embolus of the Central Artery of the Retina.—John Dunn (*Archives of Ophthalmology*, March, 1920) reports a case of embolus of the central artery which is of peculiar interest because the direct reflex response of the pupil to light was absent as long as the edema of the retina persisted, but returned after the edema had disappeared. Dunn has maintained for several years that the direct response of the pupil to light is an extracerebral reflex and that its nervous pathways are from the retinal cells to the retinal pigment cells, along this pigment layer to the ciliary region, where sensory impulses are aroused in the sensory nerves to the ciliary ganglion from this region, thence along these ciliary sensory nerves to the ciliary ganglion, in the substance of which impulses are aroused in the motor cells of the ganglion, which impulses passing outward result in contraction of the pupil. Thus he explains the phenomena of the Argyll-Robertson pupil, the behavior of the pupil in the second stage of anesthesia, the pupillary phenomena that precede death, and he believes this case to be confirmatory of his theory. Another interesting point was the preservation of a tongue-like projection of normally pink retina from the outer margin of the disc nearly to the cherry spot.

The Relation of Dust to the Spread of Tuberculosis.—H. C. Sweany and C. C. MacLane (*Illinois Medical Journal*, December, 1919) report that of 134 samples of dust taken from rooms where open cases of tuberculosis were being treated, twelve were positive. Of eighteen samples taken from the Cook County jail, three were positive. Seven positive cases were found in single and double rooms facing north, while only two were found in rooms facing south. The greatest percentage of positive samples was found in places where the greatest number of open cases were being treated. A suspension of tubercle bacilli in salt solution was killed in twenty minutes in direct sunlight with the sun's rays at an angle of fifty degrees; five hours in a film of dust in direct sunlight, five days in a south room, and seven days in a north room.

Letters to the Editors.

VENEREAL DISEASE PERIL.

NEW YORK, July 22, 1920.

To the Editors:

In your issue of April 3rd last, it was stated by an Australian that the ratio of venereal infection among the British forces was never so high as in their army of occupation during the early part of 1919. In an editorial in your issue of June 12th last it was also stated that the increase had been much greater in Europe than in the United States, and that the augmentation in cases of venereal infection in Canada had been "almost incredible," in fact, that the venereal problem was the "outstanding problem of the day." We have also been told by Dr. Joseph E. Moore, one of our military men on duty in Paris (*Journal of the American Medical Association*, April 24, 1920), that at one time he found the incidence of infection there, among our men, four times that of any other locality in the zone of warfare. As many as 70,000 prostitutes plied their trade actively in that city, and almost unmolested by the police.

Morel, also in the *Daily Herald* (London) in its issue of April 10th, tells of practices by the colored troops which were even more shocking. While thirty to forty thousand of them were occupying the enemy country, girls and women were raped and there was such wholesale infection that the hospitals were filled to overflowing with their victims. The details which he has given of practices controlled by the military authorities, in the zone of occupation, I will not give. Perhaps they still prevail there.

As these amazing statements have, so far as I know, not been contradicted, is it not our duty, as civilized beings, to have them verified or disproved?

If we as Americans are, as it seems, face to face with a real venereal peril, should we not recognize at once the menace of such European conditions, to ward them off as far as we can, and fix the responsibility for them, even if it should be shown that our sanitary authorities abroad were lax in their duties. Otherwise this subject would properly merit a congressional inquiry.

THE BORDELAISE CONCEPTION OF ENCEPHALITIS LETHARGICA.

By RENÉ CRUCHET, M. D.,
Bordeaux, France.

Adjunct Professor, Faculty of Medicine, Bordeaux, Attending
Physician, Hospital St. André.

I recall that from September to the end of December, 1915, first at Commercy, then at Verdun from December to the middle of February, 1916, and finally at Bar-le-duc, and at various successive medical military centres, where I had charge of important neuropsychiatric services, I noticed that the type of encephalomyelitis which we observed was different from the forms we had habitually encountered. In April, 1917, and prior to von Economo and Netter, we isolated with Montier and Calmette forty of these cases. These observations were published under the name of subacute encephalomyelitis (1) and the disease described was identical with the syndrome described since that time under the name of encephalitis lethargica. The following is the exact text:

Formerly it was fairly easy to diagnose the ordinary lesions of the order of cerebral, protuberential, cerebellar, bulbar, medullary, but the hypothesis of hemorrhage or softening, of tumor, diabetes or uremia, of tuberculosis or syphilis, were successively discarded. There were the central lesions, called polioencephalitis, studied by Medin and American workers, which clearly had the character of an epidemic with the characteristic abrupt inception, an elevated temperature, vomiting, marked pain, and an extensive dissemination of the paralytic disturbances, which eventually limited themselves to certain muscle groups, followed by more or less atrophy.

In various cases the febrile reaction was not intense. At times it would seem that we were confronted with a more or less attenuated form of typhoid or paratyphoid fever, but the examination of the blood did not corroborate this. The hypothesis of a fruste form of cerebrospinal meningitis did not lead to a more clear diagnosis, for the examination of the cephalorachidian fluid, even if it frequently gave a lymphocytic or albuminose reaction did not reveal anything in the way of microbes.

Whereas it was impossible not to be impressed by a certain similarity between the various cases, one was tempted to classify this disease with the attenuated affections of the central nervous system.

The general clinical characters of the disease were as follows.

ONSET.

At the onset the subjects manifest an extreme lassitude, a physical and mental asthenia; in place of a violent headache they complain of a feeling of heaviness. The fever, which occurs infrequently, is at times manifested by a feeble elevation of temperature, between 37.5° and 38° C., for a few days. In some cases the elevation is more marked, and this is interpreted as an accident in the evolution of the clinical signs, ictus, convulsions, or bulbar asphyxia. The age of the patients varies between twenty-five and forty-five years. Their inert facies, emotional indifference, semicomatose state, loss of weight, earthy appearance, at times subicteric, their lack of appetite, give the patients the appearance of being profoundly infected or toxic.

CLINICAL FORMS.

In a general way there are a complete series of clinical forms which are as follows:

1. A mental form, in which the cerebral torpor, the amnesia, the disorientation, the pupillary manifestations, the tremor, the dysarthria, even the paraphasia and the reaction of the cephalorachidian liquid, give the impression of a general paralysis of one type or another.

2. A convulsive form, in which the crises create a veritable convulsion, which generally subsides.

3. A chronic form, with all the characters of the adult form of an infectious chorea.

4. A meningitic form, in which the meningeal reactions (stiffness, Kernig, rachialgia, somnolence and vasomotor phenomena) are always associated with profound and tenacious encephalitic disturbances, which are not explained by any of the known agents.

5. A hemiplegic form, or rather hemiparetic, which, by its rapid regression and stabilization at a certain stage of its evolution, is clearly differentiated from the ordinary hemiplegia of the adult.

6. A pontocerebellar form, with ptosis, paralysis of accommodation, titubation, and a simple cerebellar form, recall the symptomatology of tumors of the cerebellum.

7. A bulboprotuberential form with various nuclear lesions of the nerves of this region, trigeminal, facial, vagospinal.

8. A mild ataxic form, which in certain ways recalls the polyneuritis of toxic infections.

9. An anterior poliomyelitis form, in which the initial characters, at least, make one think of infantile paralysis. This is an exceptional form.

EVOLUTION.

In their evolution these clinical types, which are frequently associated with one another in their development, go side by side in spite of their polymorphisms. Aside from two cases of sudden death (one during a convulsive seizure and the other by bulbar asphyxia) the regression in these subjects was slow, and the subjects, asthenic and somnolent, progressively regained their health. The sequelæ drag along and manifest themselves in relation to their anatomical lesions, paralysis or spasmodic states, cerebral fatigue, muscular atrophy, and other manifestations.

Plating of cultures and inoculation of the blood of the guineapig, as well as the examination of the cephalorachidian fluid, was systematically practised with no results. From the patient who died suddenly from bulbar asphyxia, a quantity of the material nearest the bulb was mixed with one c. c. of physiological serum and injected into the brain of a rabbit without any result. We were badly situated to conduct any pathogenic researches, for most of the patients on their arrival were entering into the period of stabilization of their disease, and when the infection was in the state of recession. The disease which was not well known would frequently be entirely overlooked, and often the symptoms would be attributed to the exaggeration of a constant fatigue.

Therefore in our first communications, we insisted upon the polymorphism of this disease which recalled in many ways Medin's disease, but was differentiated at the same time by the infrequency of the medullary localizations and the frequency of the attenuated encephalitis, the irregularity of the temperature, which was usually moderate, the ordinary absence of pain, and the persistence of the cerebral torpor. We have emphasized the inert facies of the patients, their asthenia, their somnolence, which always indicated a slow convalescence.

At the end of 1917 (1) we again called attention to this little known disease which nevertheless continued to pass unrecognized in France until the communication of M. Netter in March, 1918, upon encephalitis lethargica.

We have never ceased to consider this name as being inexact. We have shown by the foreign documents, notably English, that the trilogy of symptoms cited by Netter—lethargy, fever, and ocular paralysis—could not be applied in all cases. We have always contended that encephalitis lethargica was a particular form of diffuse encephalomyelitis, which we isolated in April, 1917 (1).

Our understanding or idea of encephalitis approved of at Bordeaux not long before, in all other respects appeared to be in accordance with the scope of a number of communications on encephalitis lethargica which have appeared in France since the end of 1919; at Lyon, Montpellier, Nancy, Angers and notably at Paris, where MM. Chauffard, Pierre Marie, Achard, Widal, Sicard, and others specifically agreed on all points we demonstrated

(clinical anatomicopathological, nosographical) and our interpretation.

Concerning the details of certain clinical forms, such as the myoclonic of the type of electric chorea of Dubini, the ideas set forth by M. Sicard tend to reinforce the original ideas we had some time ago. In 1907, I insisted upon the rhythmic character of the chorea of Dubini, and definitely separated the movements, classifying them under the name of rhythmic rather than the more vague term of myoclonia.

These marked rhythms, as we indicated in the beginning, are always symptomatic of serious cerebrospinal lesions; especially in tuberculous meningitis, and in the complications of central localization in typhoid fever, alcoholism, measles, bronchopneumonia, and other infectious diseases. One of their essential characters is their persistence in sleep or coma, contrary to those occurring in true chorea. The prognosis is invariably fatal (1).

These particular manifestations are encountered in rhythmic encephalitis and actual myoclonias, as have been described in a number of cases seen in Bordeaux, Lyon and Paris.

CONCLUSIONS.

1. Encephalitis, called lethargica in May, 1917, at Vienna and in March, 1918, at Paris, was considered and described on the 27th of April, 1917, as one of the forms of subacute or diffuse encephalomyelitis.

2. The Bordelaise concept of encephalitis lethargica, or better called epidemic encephalomyelitis or the disease of Cruchet (as it is called in the Girondine region) is that which is adopted in England, in the United States, in Italy, Spain and in the South American countries, and is also accepted in France in the large centres like Lyon, Nancy, and Bordeaux, and was finally accepted in Paris.

Early Diagnosis of General Paralysis of the Insane.—Egbert W. Fell (*Southern Medical Journal*, March, 1920) says that a change in disposition or habits in a middle aged man should always cause suspicion of paresis. A diagnosis of paresis is possible even in the early stage by a careful consideration of the mental, neurological, and serological findings.

THE SYMPTOMS OF EPIDEMIC ENCEPHALITIS STRUCTURALLY AND FUNCTIONALLY CONSIDERED.*

By I. S. WECHSLER, M. D.,

New York,

Associate in Neurology, Columbia University and Adjunct Neurologist to Mt. Sinai Hospital.

Most of the reports which have appeared on the subject of epidemic encephalitis have been limited mainly to a description of the symptomatology and pathology of the disease. The epidemic furnished extremely rich and varied material for accurate observation, and clinicians have been afforded ample opportunity for the exhibition of their diagnostic acumen. Indeed, the multiplicity of symptoms which have been recorded and the new clinical entities which have been described almost make one feel as if the clinical side has been just a bit overemphasized, while other lessons have not been sufficiently pointed out. Without in the least trying to minimize the value of the clinical and pathological studies, and they are perhaps most valuable from an immediately practical viewpoint, an attempt might be made to interpret the clinical signs and symptoms in the light of anatomy and physiology and to inquire whether any new lessons may be drawn as to the structure and function of the nervous system.

The disease has afforded one of the rarest opportunities for the study of the functions of the nervous system and possibly may throw some light on the more obscure causes of chronic degenerative diseases of the nervous system, such as paralysis agitans, multiple sclerosis and others. Some symptoms, too, such as chorea, myoclonic movements, lethargy, cataplexia or the Argyll-Robertson pupillary phenomenon and symptoms referring to the extrapyramidal system, will bear further consideration in the light of our experience with the epidemic.

Our knowledge of the structure and function of the brain is based on the study of its anatomy and embryology (ontogenesis, myelinization), on comparative anatomy, on congenital anomalies, on methods of degeneration, on direct physiological experimentation such as electrical stimulation and on the correlation of clinical signs and symptoms with structural changes caused by disease. A number of names occur as one scans the list of great anatomists, neurologists and physiologists who have contributed to our knowledge: Gall, Flourens, Bocca, Hammarberg, Goltz, Elliott Smith, Bevan Lewis, Campbell, Bolton, Hitzig, Flechsig, Brodman, Meynert, Bechterew, Wernicke, Sherrington, Cajal, Dejerine, Head, and others.

The works of these men have helped us to understand the structure and function of the brain and aided us in the intelligent interpretation of clinical findings. Neurology, more than any other branch of medicine, lends itself particularly well to study of disease in terms of anatomy and physiology pathologically affected. Instead, therefore, of merely enumerating symptoms as parts of a picture it might be wiser wherever possible to focus one's attention on the structure and function of an affected part and

correlate with that the resulting symptoms. For instance, instead of enumerating a dozen different forms of tabetic crises, we may explain them by the underlying pathology, and merely state that involvement of the lowest sacral roots will cause vesical and rectal crises, of the lumbosacral roots lancinating pains in the legs, of the vagus gastric symptoms and so on with the girdle pains, laryngeal crises, renal crises, lachrymal crises, etc. From the practical viewpoint the important thing with reference to epidemic encephalitis is to determine the etiological factor and to make sure that we are dealing with one clinical entity. The work of Strauss and Loewe bids fair to establish the former and the whole course of epidemic has given conviction on the latter.

It has been shown that the disease is a meningo-myeloencephalitis with the last greatly predominating. Whether the peripheral nerves have been at all affected is difficult to say, as no definite pathological reports have been recorded, and whatever peripheral palsies have been observed can more readily be explained by nuclear or central involvement. If, however, one accepts the cases reported as acute infectious polyneuritis and infective neuronitis the peripheral nervous system may be said to have been involved. In some cases there have been undoubted involvement of the anterior horn cells of the cord resulting in paralyses such as are seen in poliomyelitis. The involvement of the roots of the nerves, probably in a localized meningitic process, explains the frequent onset of the disease with a sciatica, a pleurisy, a trifacial neuralgia, and some recognized but at first uninterpreted radiculitis. The hemiplegias, diplegias, facial paralyses, ptoses, strabismus, are easily explained by lesions involving the pyramidal tracts, the nuclei of the seventh, third, fourth or sixth nerves. Involvement of the phrenic nerve which has been clinically observed was no doubt due to a lesion in the cervical cord, but most of the respiratory symptoms were secondary to lesions in the bulbar centres.

However, there are other symptoms and signs which stand in need of explanation. The Argyll-Robertson pupil has been encountered occasionally, although paralysis of accommodation alone and no loss of pupillary reaction to light was much the more frequent. Now, an A-R pupil is a sign of neurosyphilis, more particularly the tabetic or parietic type, and yet it was undoubtedly seen in epidemic encephalitis. We have, therefore, an acute Argyll-Robertson coming on in an acute disease, persisting for a while then disappearing. The pathology of the phenomenon is not as yet known, but we may infer that a minute hemorrhage or inflammatory focus in the midbrain, either in the nucleus of the third nerve or the Edinger-Westphal nucleus, or superior quadrigeminal or the connections between them is responsible for the phenomenon. Marina's suggestion that the lesion of an A-R pupil is in the ciliary ganglion seems to be made untenable. The cases reported early in the epidemic as exhaustion pseudoparesis may possibly have been of epidemic form and point to difficulty originally encountered in properly interpreting the Argyll-Robertson phenomenon. Paralysis of accommodation which occurred

*Observations based on material in the service of Dr. B. Sachs at the Mt. Sinai Hospital.

so frequently, at times as the only symptom and more commonly as the only persisting symptom, must be attributed to injury of the so-called accommodation nucleus which lies farthest forward at the tip of the third nerve nucleus in the floor of the aqueduct of Sylvius. It is not likely to be due to involvement of individual fibres, although it is known that paralysis of accommodation occurs in acute infections, for instance in diphtheria, in which peripheral neuritides are not uncommon.

A curious phenomenon which has been observed in the course of the epidemic was the localized mass movements of groups of muscles, particularly of the abdomen, by some grouped under chorea and by others as special myoclonic movements. Indeed, the attempt has been made to make of the symptoms a distinct clinical entity or at least to endow it with special significance. As commonly interpreted the symptom was said to be due to involvement of the lower motor neurons, that is the lower motor cells supplying the muscles. This seems unlikely, as the most common symptom attributable to an irritative lesion of that sort is fibrillation. This is a slow, vermicular movement of parts of a muscle and not the complete movement of a whole muscle or group of muscles. The irritative phenomenon must therefore be explained by a lesion higher up. It is probable that minute hemorrhagic or inflammatory foci in the higher motor cells were responsible for the myoclonic movements.

Peculiar champing movements of the jaws have been observed and they too have been included under the myoclonic movements. These can perhaps be explained by lesions in the midbrain. Experimental studies in Bechterew's laboratory, particularly by Jürman, and studies on degeneration, etc., go to prove that the substantia nigra governs the functions of chewing and swallowing. Indeed, direct stimulation of the substantia nigra *Soemmeringii* caused just such movements as were observed during the epidemic. The substantia nigra was also shown to have connections with the caudate and lenticular nuclei and opercular cortex. In view of the affinity of the encephalitic virus for the midbrain and basal ganglia and in view of the presumed function of the substantia nigra and of its connections it may not be too farfetched to attribute the champing movements to an irritative lesion in it.

With reference to the tremors, choreic and athetoid movements, we stand on somewhat firmer anatomical and physiological ground. The tegmentum of the midbrain evidently is the concentrated associational centre for these nonvolitional movements. The red nucleus of Monakow connects with the cerebellum by way of the superior peduncle; it sends fibres down to the cord by way of the rubrospinal tract, and also connects with structures higher up, particularly with the striate body. A thalamic lesion, also, may give rise to choreoathetoid movements. A lesion, therefore, in any one of these structures may be followed by tremors, choreic and athetoid movements. This is all the more likely in view of the well known cerebellar or ataxic component of choreic movements. It is difficult of course to dissociate the cerebellar component of speech, but the musculature

involved stands in associational relation with the cerebellum and a lesion in some of the pathways will account for the disturbances of speech, particularly the slow and scanning variety. Acute chorea frequently illustrates the cerebellar disturbance to a marked degree. The lesion here as well as in cases showing pure ataxia need not be in the cerebellum, but may well be in any of the numerous pathways. The absence of reports on cerebellar foci would tend to confirm this view.

The whole striatal or extrapyramidal system has been held to account for the tremors, rigidity and catatonic symptoms. (With reference to the last more will be said later.) The acute paralysis agitans, the general rigidity, the loss of associated movements, the tremors, etc., have hitherto been attributed to lesions in the extrapyramidal system. Strümpell tried to correlate Wilson's disease, pseudosclerosis of Westphal and paralysis agitans and described what he calls an amyostatic symptom complex on the basis of disturbance of that system. He stresses the disturbance of posture and of the associational activity not directly involved in motion; this has also been emphasized by other workers, particularly Ramsay Hunt. Many cases, however, of acute epidemic encephalitis exhibited apparent loss of associational movements but showed neither the rigidity nor the tremors, so that other factors, more likely thalamic, must be taken into account. The great importance of the acute paralysis agitans and the involvement of the extrapyramidal system lies in the light it throws upon the possible genesis of chronic Parkinson's disease. The disease may be inflammatory at the start and later on degenerative. The complete or partial recoveries which have been observed and the progressive conditions also throw light on the pathogenesis. Parenthetically it may be added that some patients showed simultaneous involvement of the pyramidal and extrapyramidal systems, as evidenced by a Babinski, absent abdominal reflexes, and a typical paralysis agitans syndrome.

The facial expression, or rather loss of facial expression, has been attributed to striatal involvement. This seems to the writer to be too sweeping a generalization. Omitting the pseudobulbar type, there are three different kinds of facial expression. First, there is the actual Parkinsonian facies with rigidity which becomes masklike. There is no loss of motor power, but the movements are slow, dissociated, and involve only that muscle or group of muscles which are absolutely necessary for the execution of a circumscribed movement. Other associational activity, such as movements of the eyes in smiling and speaking or that of the forehead muscles in opening the eyes, and other similar movements are altogether wanting. Secondly, there is complete bilateral paralysis, probably nuclear in origin, of the facial nerves. It is not a question of associational loss, but of absolute paralysis. Not a muscle can be moved, the wrinkles, curves and lines disappear, the face is flattened, ironed out. The want of expression is not due to inherent absence of expression but to the inability to lend motor power to its execution. Thirdly, and what seems to the writer to be more significant of epidemic encephalitis, is the listless, dull, expres-

sionless, not quite waxlike face which simulates double facial paralysis. There is no rigidity as in Parkinson's disease and no paralysis as in the double facial form. The patient can move all the muscles and even associated motor activity is present, but there is no emotional life behind it, no intellectual background. It is, if you will, a face without a soul.

The last type of facial expression probably betrayed an involvement of the thalamus. The affective life seemed to have ebbed out. Head has insisted upon the affective, emotional aspect of the optic thalamus, and it is quite possible epidemic encephalitis attacked that side of it without hitting the special sensory end stations. But in the facial expression it would seem as if the conative side of thought has been hardest hit. Intellectual activity seeks expression in motor activity; this is most marked in the face and there any interference is most easily detected. Other motor activities such as gestures and postures also form part of the conative tendency; a general inhibition of all of them was noted in epidemic encephalitis. There seems to have been a dissociation between thought, emotion and motor activity and a considerable slowing down of each. The thalamic, affective disturbance in epidemic encephalitis often dominated the whole clinical picture or furnished the background against which were silhouetted motor, sensory and psychic disturbances.

Other syndromes were observed from time to time and they are equally interesting although their explanation is less speculative. Unilateral tremor and paralysis of the oculomotor, the so-called Benedict syndrome, owed its existence to a lesion in the tegmentum which involved the red nucleus and the third nerve nucleus or its fibres which traverse the nucleus ruber. A true Weber's syndrome paralysis of the oculomotor causing ptosis, external strabismus, fixed, dilated pupil, etc., on the same side of the lesion, and hemiplegia on the other side—was occasionally encountered. This of course was due to a lesion in the crus which compromised the corticospinal fibres and its traversing oculomotor nerve.

In a few instances one noticed conjugate deviation of the eyes. It is fair to assume that the lesion was most frequently in the midbrain and pons although there are numerous locations in the brain which might account for conjugate deviation, and in view of the numerous inflammatory or hemorrhagic foci which were found scattered in pathological sections such an assumption is not out of place. In the second frontal convolution there is one centre which if affected may give uncomplicated deviation of the eyes to one side. The same result may follow upon lesions at the knee of the internal capsule, but pyramidal tract signs would be associated with the ocular symptoms. Some authors maintain that there is a centre for conjugate deviation in the parietal lobe and a few clinicians have diagnosed lesions, such as tumor and abscess, in virtue of that symptom. This, however, is still a matter of dispute. A fourth place causing paralysis of gaze is in the hypothalamic region involving the fibres to the oculomotor, but here we get a vertical paralysis. Involvement of the pes lemniscus superficialis and profundus also gives

paralysis of gaze. A lesion in the sixth nerve nucleus which controls not only the external rectus of one side but the internal rectus of the other results in paralysis of lateral gaze. This form of conjugate deviation is frequently called the syndrome of Foville. Finally, lesions in the posterior longitudinal bundle and the Deitero (vestibular) oculomotor pathways will also give conjugate deviation. In each instance, however, the presence or absence of other symptoms helps to determine the site of the lesion. For instance, nystagmus and ataxia accompany lesions in the vestibular pathways, a facial paralysis in the case of the posterior longitudinal fasciculus and so on with the others.

Attempts have been made to explain the bladder disturbances, particularly retention, by means of lesions in the midbrain. There is some ground for believing that there is a centre there which controls the bladder function, but more definite observations are required to establish the fact beyond peradventure. The same may be said of some disturbances of function of the sympathetic system, such as vasomotor changes, sweating, etc., which have been observed. Certainly the midbrain and bulb and very likely the cortex stand in intimate connection with the general sympathetic and autonomic systems. In the case of urinary retention it is quite possible that the brain, because of the general affection, is unable properly to receive and interpret afferent sensory stimuli or send out efferent motor impulses.

The question of catatonia, catalepsy or *flexibilitas cerea*, has been variously interpreted. It is doubtful whether one can altogether explain it, as has been attempted, by involvement of the extrapyramidal system. There is not that mimic and other rigidity which one is accustomed to see. One might invoke the cerebellar mechanism (particularly in view of the asthenia, which could be so interpreted) but that, too, does not give the desired explanation. More likely is it that we are dealing with a true cerebral condition, or rather interference with cerebral function and the consequent liberation of uncontrolled, unconscious activity. Theoretically, dissociative hypnotic catalepsy furnishes a parallel. But there are some pathological facts which may explain the catatonia. Southard has demonstrated lesions in the supracortex or neopallium in the parietal regions of brains of patients who suffered from catatonic dementia præcox. Whether minute lesions or general toxic affection, edema, etc., can explain the catatonic conditions in encephalitis cannot be definitely stated, as Southard's work has not been altogether confirmed; but inferentially one may speak of the cortex as the probable seat of the lesion in catatonia. It should be recalled that Alzheimer speaks of a gliosis in the lower layers of the cortex in catatonia.

The coma in epidemic encephalitis has given rise to a good deal of discussion. The fact is that it differs from the comas with which one is familiar. Indeed, it may be doubted whether the patients are either sleepy or comatose. What strikes one most forcibly is a want of attention even after momentary well coordinated responses to stimuli, an indifference, an utter absence of emotional response. There seems to be a paralysis of the emotions. There is

general apathy, a seeming indifference to general sensory stimuli. Even at the risk of riding the thalamic hobby horse too hard one might invoke the aid of a disturbance in affective control of the thalamus as an explanation for the puzzling condition. Certainly the corticothalamic connections are affected. In very severe cases, the patient is a vegetating automaton without either intellectual or emotional life, barely showing a human flicker and not betraying the slightest sign of struggle, physically or psychically.

Some have attributed somnolence to disturbance of the pituitary; others referred it to the pineal gland. All these suggestions are interesting but have little to recommend them. Nobody has observed actual signs or symptoms of involvement of either of the hypophysis or epiphysis cerebri. It may be urged that the functions of the brain, more particularly the higher function, are not limited to any particular part and that a general disturbance accounts for the alteration in the psychic and emotional life of a person suffering from epidemic encephalitis. Perhaps disturbance in the neuroglia may account for some of the general symptoms. Achucarro's view that the neuroglia is a structure or organ of internal secretion may satisfy those who are speculatively inclined, although few pathological changes have been reported in the glia structure of brains which have been studied closely.

The term manic has been frequently employed to describe the mental condition of patients with encephalitis. In most instances the term was very unfortunate. What the patient suffered from was delirium—an infectious or toxic delirium such as is seen in other diseases. They did not have a true psychosis despite the fact that they seemed to have delusions or hallucinations. To be maniacal in a delirium does not mean that the patient has a psychosis. It is only when mental symptoms persist after the acute febrile condition has subsided that one may speak of a psychosis as the result of epidemic encephalitis. Such cases have occurred, it is true, but they have been extremely rare. The same thing may be said of convulsions in the course of the disease. The common term epilepsy is not strictly applicable.

The whole course of the disease proves that it is a general infection with selective affinity for the central nervous system. The fever is in favor of such a conception. The fact that most of the pathological changes are mesodermal—meningeal inflammation, perivascular infiltration, small hemorrhages, occasional thrombosis with secondary necrosis, edema, etc.—also points in that direction. Finally the successful reproduction of the disease in animals by intravenous inoculation (Strauss and Loewe) furnishes very strong evidence. The morbid changes resemble those found in other infectious diseases of the nervous system. The similarity in the pathology of many diseases of the nervous system of different etiology suggests that it is the underlying histological structure of the cerebrospinal axis which mostly determines the reaction and not the individual causative factor. The histopathological picture seems to depend more upon the question of whether the mesodermal or ectodermal structure is mainly involved.

1291 MADISON AVENUE.

ENCEPHALITIS LETHARGICA.*

A Study of Its Clinical Aspects.

By JOSHUA H. LEINER, M. D.,
New York,

Adjunct Attending Neurologist, Lebanon Hospital; Attending Neurologist, Central Neurological Hospital, Blackwell's Island.

In the early part of 1917, Von Economo and Von Wiesner (1), of Vienna, reported a disease affecting the central nervous system, of which lethargy was the most prominent symptom. Von Economo thereupon coined the syndrome, encephalitis lethargica. This name is incorrect and has other shortcomings, but for the present at least the disease will have to be so called. It has been found, however, that eighty per cent. of the cases have shown lethargy.

That this is not an entirely new disease is shown by Crookshank (2), who pointed out that epidemics of disease resembling encephalitis lethargica occurred at various times and under different names in medical literature, going back at least 450 years. It seems that whenever it appeared, it was always thought to be a new disease. Linnæus called it raphania, and thought it was due to radish seeds; the Germans thought it was due to contaminated meats, such as sausages. Albrecht, in 1695, described it as the lethargica fever with disseminated eye signs. In the sixteenth century it was seen in Italy, and called *mal mazuze*, or sickness of sleep. In 1890 epidemic encephalitis swept over the Lombardy Plains of Italy, and even Hungary, where it was called nona. In 1917 it was called the mysterious disease, in Australia.

The relationship of epidemic encephalitis to influenza has been pointed out by Jelliffe (3), Menninger, and others. It has been linked with botulism and atypical poliomyelitis in the early days. Bassoe (4) thought the histology bore some resemblance to the trypanosome infection. However, it is a disease entity, with its own peculiar pathology and bacteriology.

Next to the protean clinical symptomatology displayed as a result of the syphilitic virus involving the central nervous system, in the variety of clinical symptoms engendered in this disease it easily ranks second. Because of this fact for the present at least, each writer establishes his own classification as a working hypothesis, in recording his cases.

AGE AND SEX.

A case of congenital epidemic encephalitis was reported by Harris (5). The mother, aged twenty-eight, was a victim of this disease, and gave birth to a child that seemed excessively drowsy. On the third day, a lethargic condition set in. This lasted for several days with subsequent recovery. The youngest patient recorded as having this malady was four months old, the oldest was aged ninety-six years. The greatest number of cases are found in those who seem robust and healthy. Its most frequent occurrence is between the ages of twenty and thirty, which bears this out. Males are more often affected than females.

*Read before the Bronx County Medical Society, May 19, 1920.

GENERAL SYMPTOMS.

Lethargic encephalitis is an acute disease affecting the central nervous system. Like all acute infectious diseases, it may appear as a fulminating type and the patient dies within a few days, or, as in the majority, as a long drawn out illness.

The general symptoms begin with the patients being either apathetic and drowsy or showing an initial exhilaration. They may continue to be drowsy and walk about in this way. In two cases of this variety the patients walked into the Lebanon hospital clinic, showing acute Parkinsonian symptoms, i. e., in their gait and attitude, and they had tremor, rigidity, and rise in temperature. One of the patients in addition showed an involvement of the right sixth nerve. This condition may then become stationary, or take the form of pathological sleep and lethargy. The exhilarating type shows an excessive energy at work or at play, which may later merge into the drowsy or sleeping state. Dr. Richman, who had epidemic encephalitis in 1918, showed periodical states; either he was asleep or very restless. He showed the most marked restlessness that I have ever seen. He kept turning continuously in bed pleading for opiates. Headaches are severe in some cases; vomiting and giddiness in others. Many patients complain of neuralgic pains, and pain in back of the neck, together with suboccipital tenderness. In these cases Kernig's sign could often be elicited. Coarse tremors were often found in the fingers early in the infection. A severe chorea would at times usher in the disease. The temperature would rarely rise above 101° F. Someone has characterized this infection as a low smoldering fire. The terminal states were often marked by higher temperature, which was frequently a complication and not a picture of the disease proper. A good many patients died from hypostatic pneumonia.

LOCAL SYMPTOMS.

The local symptoms are dependent upon the area involved. The disease seems to have a predilection for the mesencephalon, and the basal ganglia. This fact accounts for the frequency of third nerve involvement, with ophthalmoplegias resulting in early diplopia; the red nucleus, and superior peduncular fibres, showing the chorea, athetoid movements often remaining as residual symptoms; the tremors, Parkinsonian rigidities, a picture of corpora striata invasion, particularly of the pallidal system, which controls the automatic and associated movements; and finally the cutting off of all centripetal stimuli to the thalamus, resulting in sleep. Climenko (6) tries to explain this phenomenon on the basis of a toxic involvement of the pituitary which leads to a temporary suspension of function, similar to hibernation, which was first noted by Cushing. If the neighboring internal capsule is affected with involvement of the corticospinal tracts, we have hemiplegia and other similar manifestations. Again the pontine and medullary nuclear implications give rise to their respective symptoms.

The toxic involvement of the endocrines, autonomic, sympathetic systems is striking adrenals being particularly affected and showing the severe constitutional toxemia. Hypoadrenia with exhibition

of Sergent's white line has been noted by Climenko (6), Goldmark, and myself. I have witnessed its disappearance in a patient with marked asthenia after the administration by mouth of whole adrenal gland. In the service of Dr. Goldmark at the Lebanon Hospital, hypodermic injections of adrenalin led to an improvement in blood pressure, pulse, and the disappearance of Sergent's white line. Alexander and Allen (7) observe strange vasomotor phenomena. A child, aged five and a half years, who had epidemic encephalitis, showed half of the ear flushed, while the remaining half was blanched white, also flushing of only one cheek at a time and a sudden cyanosis of one hand, while the radial pulse was equal on both sides.

PSYCHIC TYPE.

CASE I.—I was asked by Dr. Gitlow to see a male patient, aged forty-five. For three weeks his temperature never exceeded 101° F. No pathological changes were found in the viscera. Neurologically he showed a marked suboccipital tenderness, a slight facial droop on the right side, and a right Babinski that was not constant. Psychically his memory and retention were poor. He showed an incomplete Korsakoff syndrome. In addition he had delusions of persecution, of a sexual accusatory character. I performed a lumbar puncture, and the fluid came out under very high pressure. The fluid was clear. The Wassermann was negative. The patient recovered completely in a few weeks.

There are now two girls at the neurological clinic of Mt. Sinai Hospital, one aged twenty and the other twenty-one. Both gave a history of having had colds, accompanied by fever, extreme restlessness, and insomnia. Both show a psychosis of the manic depressive type, one belonging to the cyclothymics with alternating periods of depression and excitement. Both patients showed a suppression of their menstruation, one not having menstruated for five months and the other for three. Neurologically they showed negative findings.

Here we have cases of a toxic psychosis, which gave rise to hallucinations, delusions, catatonic states with *flexibilitas cerea*, reminding one of the catalepsies in dementia *præcox*. Kinnier Wilson reported a patient who showed a typical *witzelsucht* (8), Climenko's (6) case showed a true Korsakoff syndrome. It must be observed, however, that as a general rule, even at the height of the disease, during pathological sleep, the memory is surprisingly accurate, and the mental attitude one of absolute indifference. The facies depict no emotional play, due perhaps in some cases to facial nuclear, supranuclear or nerve involvement, and in others to striatal tract implication as in Parkinson's disease, with its rigid masked features.

CEREBRO CEREBELLAR TYPE.

Alexander and Allen, who have collected the data up to date, state that the oldest patient who contracted this disease was aged sixty-two.

CASE I.—This female patient was sixty-five years of age. The history shows that four grown up children had so-called influenza. They recovered, when the mother, who was nursing them, contracted the disease. She had pneumonia, was cared for

by Dr. Handleman, and was up for a week, when she became listless and drowsy. When I saw her she was in bed, the face was masked, the eyelids were closed; she would raise them half way when requested. When she was requested to do this a number of times in succession, this effort would be followed by an inability to open the lids, reminding one of the observation made by Hall (9) and Foster Kennedy (10), that the condition resembled myasthenia. The pupils reacted to light. I could not elicit any other test that required the patient's cooperation. Her pharyngeal and uvular reflexes were absent. The neck and both upper extremities were rigid. The radial and triceps reflexes were obtainable. The lower extremity on the right side was drawn up and rigid. The knee jerk on this side could not be obtained because of an anomalous condition of the quadriceps tendon on that side. The left knee jerk was present, but the extremity was rigid. The right ankle jerk was absent.

She was admitted four weeks later to Lebanon Hospital, where she presented a typical lethargic encephalitis. There were double facial involvement, tremor of digits of both hands, and rigidity of both upper and lower extremities, together with stupor. Repeated questioning would sometimes elicit a whispering monosyllabic reply. Her temperature was never above 101.5° F. She died of a terminal hypostatic pneumonia, after a ten weeks' illness.

CASE II.—This case is of the fulminating variety. The patient was seen by Dr. Bennet three days before I saw her. She was a young married woman aged twenty-four, who first showed some catarrhal symptoms, headache and insomnia. She showed an acute Parkinson's disease with marked rigidity, tremors, suboccipital tenderness and Kernig's sign. The same day she was admitted to Lebanon Hospital, where she died in eighteen hours. A postmortem examination was performed. The piaarachnoid showed marked congestion over the convexity and base. A slight exudate was seen. The ependyma of the fourth ventricle was found congested. When I cut down into the tissue to examine the basal ganglia, I found nothing upon gross examination. The brain was left to be sectioned, but unfortunately the porter in trying to obtain new jars threw it away. Perhaps we could have confirmed Dr. Ramsay Hunt's findings that the lenticular nucleus, especially the globus pallidus, is involved in those cases that manifest acute Parkinsonian syndrome.

CASE III.—This case is of interest because of acute onset of cerebellar involvement. Male, aged thirty-six, had a cold for three days, together with insomnia and restlessness followed by drowsiness. I saw him three weeks later. He then showed a partial ptosis of the left eye, a nystagmus, with greater amplitude to the left, and a dysdiadokokinesia of the left upper extremity, together with a certain amount of hypermetria in performing the heel to knee test, on the left side. When standing he fell to the left. When walking he reeled to the left. Dr. Luttinger, his family physician, stated that his temperature hovered between 99° F. and 100° F., and never above this. There was no visible sign of involvement of the corticospinal pathways.

MYELONEURITIC TYPE.

Here the central grey and the white matter, the root ganglion and nerves show involvement.

On May 4, 1920, Dr. Walter Kraus presented a case before the New York Neurological Society, which showed a distinct involvement of the fifth and sixth nerves of the cervical region of the cord, involving the anterior horn cells, with a resulting winged scapula, and atrophy of the muscles of the arm and forearm. The early symptoms were those of epidemic encephalitis. This case showed the protean nature of the disease, and the thin ice we were treading in trying to differentiate this from a classical case of acute anterior poliomyelitis.

CASE IV.—This is a case of the radicular type. H. S., twenty-three years old, became sick the early part of January, 1920, his teeth pained him and he had pains in his ear. Five days later when I saw him he complained of severe pain in both arms and hands, and in the cervicodorsal region of his back. He presented wild choreiform movements of both upper extremities and of the lower extremities to a lesser degree. Accompanying this there were continuous chewing movements, and also swallowing. His speech became nasal in character, and he often stammered. On examination, his pupils were contracted, the right larger than the left, and reacted to light sluggishly. Nystagmoid movements were present, and the left sixth nerve was paretic. A history of diplopia was elicited. A distinct right facial paralysis was observed. Suboccipital tenderness was present, together with a slight stiffness of the neck. The right abdominal reflexes were absent. Knee and ankle jerk were diminished. A slight Kernig was elicited; no Babinski nor Oppenheim at this time. On February 10, 1920, I was told that he was drowsy for three days during the preceding week, his temperature was 101° F. He complained bitterly of pain which prevented him from sleeping. This was present in the forearms above his wrists and external surface of his arm and forearm, corresponding to C5 and C6, the right being more painful than the left. The chorea had ceased, and a coarse tremor with occasional jactitations was present in the digits of both hands. His facial paralysis was less apparent. The knee jerks and ankle jerks were more active. No Babinski was present, but an Oppenheim was obtainable for the first time, i. e., four weeks after the onset of the illness. He showed a distinct level of hyperalgesia from the fifth to the seventh cervical.

On February 20, 1920, his pupils were more dilated, reacted readily to light and in convergence. But he now saw objects one above another. The facial paresis was greatly improved, the abdominal reflexes were all present; knee jerks were lively, the Oppenheim was present, and a Gordon reflex was also elicited on the left side, but at no time was a Babinski plantar reflex present. He now complained of pain only in the right hand, limited to the ulnar nerve distribution. He showed no tenderness of the nerve trunks. On February 26th his status was about the same, but his sensory cord level was now down to the first dorsal. In the middle of March, 1920, his double vision had entirely disappeared;

the optic discs were not involved. Coarse tremors were still present, and an Oppenheim of the left lower extremity was elicited. He still complained of burning pain in the back of his neck.

CASE V.—This case showed both a radicular and a myeloneuritic involvement. A married woman thirty-two years of age was sick for seven weeks before I saw her. There was a history here of diplopia, and of having been in a lethargic state. The patient's pupils were equal and moderately dilated, reacting promptly to light and accommodation. Ankle jerks were present bilaterally, but the left knee jerk was diminished. She showed an atrophy of the left thigh group and a trophic skin disturbance. Severe pain was complained of in the cervical region, and a level of C5 and C6 hyperesthesia was present. There was segmental hyperesthesia corresponding to this level, involving the right deltoid and external surface of right arm. A Lesegue sign was present in the left lower extremity, together with tenderness along the sciatic. Another line of radiculitis was found at the lower lumbar and upper sacral region. The bladder was involved and this led to a cystitis.

CASE VI.—L. L., female, aged seventeen, a patient in the neurological clinic, in Dr. Climenko's service, of Mt. Sinai Hospital. She came in with her head resting on her left shoulder. A history of having been five weeks in bed was given, together with restlessness and insomnia. For the past three weeks she had had pain in the left side of her head and in her left arm. This arm had a pulling sensation; an occasional twitch was visible. Examination revealed a weakness of the left side of the face, a weakness of left upper extremity, and the head was deviated to the left. Pain was present in both upper extremities on passive motion. There was a distinct line of hyperalgesia of C5 and C6. This girl improved gradually, and she is holding her head erect again. She had not had her menses for the past three months.

PATHOLOGY.

The basic pathological condition can be epitomized to a vascular congestion and perivascular infiltration especially around the veins. A predominating number of lymphocytes are present, but plasma cells and polynuclear cells are also present. These hemorrhagic areas may be minute in size, and can hardly be detected macroscopically. The changes in the surrounding nervous parenchyma show different grades of degeneration, even neurophagia being noted, but to a far less extent than in poliomyelitis, as noted by Marenesco; another point is, there is less destruction of the parenchymatous tissue than in poliomyelitis. This has also been noted in poliomyelitis. This pathological condition has been noted in every portion of the affected nervous tissue.

BACTERIOLOGY.

Von Weissner recovered a gram positive diplo-streptococcus, which, it is stated, will produce somnolence when it is injected in monkeys. Wegforth and Ayer have inoculated monkeys with cord infiltrates from the infected human as well as spinal fluid injections, and their results were negative.

The most promising work in this field of investi-

gation, which is of the highest type of scientific endeavor, and is bringing results that are most convincing, is the work of Strauss and Loewe (13, 14). They have fulfilled Koch's law in every respect. They have produced lesions in monkeys that are characteristic of the disease, by means of the emulsion of the human infected brain, by filtrates derived from the nasopharynx of sufferers of this disease, and isolated an organism that is small and globular in shape, appearing in diploforms, chains or in clumps. The inoculation of this organism has produced the disease. The organisms were then recovered, and passed through generations of monkeys and rabbits. I have personally seen these globoid bodies, observed the stuporous animals, and the macroscopic and microscopic lesions, engendered by the organism. For diagnostic methods in the detection of this malady they have lately introduced a Shick epidermal reaction. The observation should be made, that the organism in some characteristics, resembles the one found by Flexner and Noguchi in poliomyelitis.

In consideration of the residual symptoms that this malady leaves behind, it is too early to see if they will remain permanent. On the neurological service of Dr. W. Leszynsky in Lebanon Hospital there is a man who has shown attacks of *petit mal* following encephalitis. At the Montefiore Hospital there are two cases of residual postencephalitis, one patient showing a Parkinsonian and the other a hemiplegic syndrome. The patient with cerebellar involvement, whose case is mentioned in this paper, still shows vertigo, when looking upward. One must therefore be guarded in the prognosis. The patient with a radiculitis with a sciatic neuritis showing atrophy of her muscles is a case in point. There is no true cerebral type nor any pure type in this affection. The cerebral form may combine with the radicular but it is the same disease.

In conclusion I wish to point out a rather obscure type of this malady which Dr. Reilly mentioned, and one case of which was seen on the neurological service of Dr. Leszynsky, in the Lebanon Hospital. This male patient gave the clinical picture of a man in coma, either of the nephritic form or of the diabetic type. In addition to this he showed glycosuria. We know that a great proportion of sufferers of this affection have shown sugar in the urine. Dr. Reilly mentioned a few cases of this type that came under his observation. This patient showed very marked spasmodic abdominal muscular contractions. These contractions have been noted in different parts of the body, resembling myoclonic muscular contractions. Dr. Abrahamson has pointed out that the muscles so affected always corresponded to the line of spinal hyperesthesia elicited.

TREATMENT.

The treatment is purely symptomatic. Some efforts have been made in the use of serums and vaccines, but no success has attended this field of endeavor. Lumbar puncture at times seemed to afford some relief for the symptoms, but this was short lived. It should only be used where there is marked meningeal irritation. Good nursing is the best treatment.

In the residual symptoms that this disease engenders, massage, which should be applied lightly, is often indicated. In those cases that show contractures, the earlier the immobilization with overcorrection the better the prognosis. I wish to take this opportunity for thanking Dr. William Leszynsky, Dr. Hymen Climenko and Dr. Carl Goldmark for allowing me to quote some of their cases.

1187 BOSTON ROAD.

ENCEPHALITIS LETHARGICA.*

Report of Eleven Cases.

BY SAMUEL SCHWARTZ, M. D.,
New York.

Through the courtesy of Dr. Neff, I beg to present before you a paper reviewing the cases of encephalitis lethargica at the Harlem Hospital. Before proceeding with our own cases, I shall first give a résumé of the literature on the subject.

DEFINITION.

Accepting Sainton's definition we may classify it as "a toxic infectious epidemic syndrome characterized clinically by triad lethargy—ocular palsies and a febrile state—and anatomically by a more or less diffuse encephalitis most marked in the gray matter of the midbrain."

HISTORY.

In the middle of 1917 Von Economo reported a number of cases appearing in Vienna in epidemic proportions characterized by somnolence—almost simulating sleeping sickness, and very illogically called it encephalitis lethargica, for not all the patients are lethargic. Many of them really suffer from insomnia and are very restless. In March, 1918, Breinl reported nine cases observed in Australia. About the same time that these observations were being made in Australia, similar cases were under investigation in France and England, and later reports from Italy and Uruguay give evidence that the disease was worldwide in its distribution. This disease is not a new one, as similar epidemics

have been reported as early as 1712 and others in 1891, following pandemics of influenza. So we see that the present epidemic first appeared in eastern Europe and in Australia, then it spread westward reaching France and England early in 1918, and in this country in the fall of the same year. The first case in this country was observed in Major Tasher Howard's service at Camp Lee, Va., in November, 1918.

PATHOLOGY.

We have had opportunity to examine the brains in two cases in which complete necropsies were performed. The appearance of these two brains was very similar. The gross changes consisted of edema and marked congestion. The histological changes were also similar in the two cases and were mainly found in the basal ganglions and brain stem. They consisted principally of dense accumulations of mononuclear cells around the vessels and of small hemorrhages. There was little evidence of necrosis or of extensive tissue destruction, in which respect this disease differs from poliomyelitis.

SYMPTOMS.

The outset of the symptoms was always insidious. The first suggestive symptom has been blurring of vision, with more or less definite diplopia, together with progressive listlessness which when pronounced has been called lethargy. The facies gradually becomes extremely characteristic with masklike immobile features, half open eyes and a fixed, more or less distorted position of the mouth. The patient does not sleep as much as is indicated by the sleepy expression. In fact, some of the patients actually suffer from insomnia. Thus we see that the lethargic appearance is only a sign of the involvement of the cerebral mechanism. In one of our patients there developed distinct choreiform movements with labored respiration and weak, rapid pulse. Retention of urine was a common symptom observed in our cases. The urinary apparatus has its centre, according to recent investigation, in the basal ganglion, which is the favorite site of the inflammatory changes in this disease. Fever is usually present to a variable extent, but like the lethargy does not bear a direct relation to the amount of infection present. Headache, malaise and weakness are common symptoms, noticed in the early stage of the disease. Orientation was usually unaffected just until death, and a very important symptom was a sense of euphoria which almost all of our patients had when aroused and questioned as to their condition.

REPORT OF CASES.

Our own experience at Harlem Hospital with encephalitis lethargica dates back to September, 1919.

CASE I.—P. S., male, white Russian, aged thirty-eight, was admitted to the institution September 28, 1919. Chief complaint was headache of two weeks' duration. His daughter was at that time at Mount Sinai Hospital, ill with encephalitis lethargica. His headache came on with an upset stomach, felt very weak, was sleepy, and could not see with the right eye. Physical examination revealed the patient in lethargic state. Bilateral ptosis was present, the tongue and mouth deviated to the right,

*Read before Harlem Hospital Medical Society, April 6, 1920.

there was diminished power in upper extremities, Kernig and Babinski were positive. There was left facial weakness and the neck was rigid.

The laboratory findings were as follows: Blood, white blood corpuscles 10,000, polynuclears sixty-one per cent.; lymphocytes thirty-nine per cent., blood pressure 140, 95, urine negative, blood and spinal Wassermann negative, spinal fluid came out under no pressure, was contaminated with blood, twenty-two cells per mm., Fehling slightly positive, Noguchi slightly positive, no organisms were found; temperature 103° to 99.4°, pulse 112 to 90, respiration 24 to 20.

His eyes, examined by Dr. Cohen, showed myopic changes in the left eye, with internal strabismus, dislocated right calcareous lens with complete retinal detachment. The pupils were equal and reacted to light and accommodation. There was a calcareous deposit in right anterior chamber of the eye. Later findings showed ocular paresis, urinary retention, left abdominal muscles less active than right. The patient was discharged as cured October 22, 1919. In this case the early tendency to oculomotor disturbance indicates primary involvement of the upper part of the brain stem around the aqueduct of Sylvius and the third ventricle.

In reviewing the literature of encephalitis lethargica complicating pregnancy I find only eight cases reported. The mortality is far higher in females than in males. The mortality rate in pregnant women is very high.

Out of the eight cases reported five of the patients died, one recovered, and in the other two the outcome was not reported. In the Harlem Hospital we had four cases complicating pregnancy; three patients died, one recovered.

CASE II.—B. M., aged twenty-six, white, Hungarian. Admitted January 5, 1920, to Dr. Broadhead's service for delivery of second child. On January 6th, the patient complained of headache, pain in neck and vomiting. Dr. Langrock examined the patient and stated that her pregnancy did not account for her condition. Spinal puncture was performed and twenty c. c. of clear, colorless fluid under moderate pressure was withdrawn; twenty cells to the c. mm., Noguchi positive, Fehling negative, no organism was demonstrated. The urine was negative. The patient became irrational. The reflexes were exaggerated. The Kernig was positive, Babinski positive. The patient had urinary retention and died January 8, 1920.

CASE III.—L. F., female, aged twenty three, white, Hungarian. Admitted February 7, 1920, because of pain in back. Was sick at home for a week, and on admission a diagnosis of pneumonia was made. Physical examination revealed well developed physique in lethargic state. There was no evidence of consolidation in the lungs. The posterior pharynx and tonsils were the seat of a marked inflammatory process with large amount of mucus exudate. The neck was rigid, Kernig positive, left sided facial paralysis. On February 10th, there were automatic movements of left upper extremities, and a clonic convulsive action of right lower extremity.

The fundus of the bladder reached to the umbili-

cus. The patient was catheterized and sixty-eight ounces of urine withdrawn. The fundus of the uterus was about three fingers below the umbilicus, and Dr. Broadhead believed that she was probably four months pregnant.

Laboratory findings: Blood—red blood cells, 4,200,000, white blood cells, 13,200, polynuclears eighty-six per cent, lymphocytes, fourteen per cent., urine negative. The spinal fluid came out under moderate pressure clear and colorless. There were thirty cells to the c. c., lymphocytes 100 per cent., Fehling positive, Noguchi negative, no organism demonstrated. Temperature 103° to 98°, pulse 122 to 138, respiration 26 to 34. The patient died February 11, 1920.

CASE IV.—C. D., white, aged 20, married, pregnant, was sent in by Dr. Cherry to Dr. Hayne's service, March 18, 1920, with tentative diagnosis of toxemia of pregnancy. The patient had enjoyed good health throughout her pregnancy. Two weeks ago she began to have severe headaches, sleeplessness, and vomited once. She also noticed that her vision was defective. For past five days she has been extremely drowsy, and hard to waken; and for last forty-eight hours has been picking at the bed clothes, and was irrational. Dr. Garretson examined the patient and reported the following:—"Cranial nerves negative. Can open both eyelids, left appears slightly paretic, extrinsic ocular muscles apparently balanced. Reflexes, upper extremity normal and equal, lower extremities, patella reflexes absent, plantar present and normal, sensation responds to tactile and pain normally." The patient gave no history of convulsions and there was no edema of the lower extremities. Laboratory findings: Urine, 3 plus albumin, blood pressure systolic 175, blood, white blood corpuscles 16,600, polynuclears, eighty-five per cent., lymphocytes fifteen per cent, a spinal puncture was performed and gave a clear, colorless fluid under slight pressure. There were no cells, Noguchi was slightly positive, Fehling positive, no organism was demonstrated. The patient died March 21, 1920.

CASE V.—A. G., white, single, eight months pregnant. Admitted February 13, 1920. Complained of headache, pain in back of neck and fever which began two weeks ago. She became drowsy and felt so weak that she had to stay in bed. Physical examination revealed adult female in lethargic state. The pupils were equal and regular, reacted to light and accommodation, no strabismus, rotatory nystagmus of right eye, with weakness of right levator palpebræ muscle. The uterus was enlarged to the size of an eight months' pregnancy. The knee jerks were present, Kernig present, Babinski ankle clonus and Brudzinsky not obtained. Lumbar puncture performed and twenty-five c. c. of clear spinal fluid obtained under no pressure.

The laboratory findings were, thirteen cells to the c. m., Noguchi negative, Fehling positive, no organism was demonstrated. The urine showed a weak trace of albumin, no sugar, granular casts with red and white blood cells. The patient was transferred to the obstetrical ward, pronounced cured, where she gave birth to a baby boy March 26, 1920.

CASE VI.—M. B., aged nineteen, white, married, Austrian. Admitted January 19, 1920, because of marked headache and weakness, loss of appetite and general malaise. Physical examination revealed a poorly developed female, anemic, and in a lethargic state. The muscles of the neck were rigid, Kernig positive. A clinical diagnosis of tuberculous meningitis was made and spinal tap was performed, twenty c. c. of clear colorless fluid under pressure was withdrawn. The laboratory findings were, twenty cells to the c. mm., Fehling negative, Noguchi slightly positive, no organism was demonstrated. The temperature was 102° to 104.5°, pulse 150 to 155, respiration thirty-four to forty. The patient died January 22, 1920.

CASE VII.—M. G. aged thirty-two, U. S., married, admitted January 27, 1920. Ten days prior to admission she complained of headache and pain in orbital region. She also complained of diplopia which lasted four days. On the fifth day the diplopia disappeared and the patient went into a lethargic state. Three days ago there was noticed a muscular twitching of the face and tongue, and the protruding tongue was deviated to right side. This condition kept up till February 3rd, when the temperature came down by lysis from 102° to normal and the patient was discharged as cured.

CASE VIII.—This case differs from the others by the absence of somnolence and the presence of choreiform jerking movements. The patient was irritable and had an anxious expression. The patient was a young girl, white, fifteen years of age, admitted February 18, 1920, because of pain over the head which had continued for two weeks. Had diplopia ten days ago. Physical examination revealed young girl well developed, with labored breathing. Herpes were present on the lips, ptosis of right eyelid, pupils were equal, Kernig positive, no Babinski or Brudzinsky. The next day the patient became violently delirious which necessitated restraining her in bed. She had many absurd illusions. While the lumbar puncture was done the patient seemed to pay no attention to the entrance of the needle. A clear, colorless fluid under moderate pressure was withdrawn.

The laboratory findings were 350 cells to the c. mm., Noguchi positive, Fehling positive, no organism was demonstrated. Blood, white blood cells 23,000, polynuclears 84 per cent., lymphocytes 16 per cent., temperature 103°-100°, pulse 120-145, respiration 42-20. On February 21st the patient went into coma and died February 22nd.

The necropsy was performed by Dr. Cassasa, and he found the following: scalp negative; skull negative; dura normal. Brain: Extreme congestion of brain; vessels in the sulci markedly dilated and branches over the convolutions markedly congested. The congestion was of a crimson color. The sulci and convolutions were very well marked. There was no free fluid in the pia arachnoid meshwork over the cortex of brain. The knife was passed in a horizontal plane in a lateral direction over corpus collosum. The first three or four cervical segments of brain were also removed. The brain and cord were put in formalin to be examined for epidemic encephalitis.

The right pleural sac was completely obliterated by old adhesions. The right lower lobe was firmly adherent to the chest wall and diaphragm. In the left pleural sac, over lower lobe there were old adhesions; section of right lung; upper and middle lobes normal, showed no congestion or edema. The right lower lobe over its entire extent was markedly congested and consistency increased. There was no distinct granulation on section. The upper lobe of the left lung was normal; no congestion or edema. Along the costal vertebral border of the lower left lobe there was an area of congestion about an inch deep; on section this area was black, not granular and slightly firm.

There was no dilatation of the right heart. The pericardial sac was normal, heart muscle good color. Right and left heart contained a soft, dark red blood clot. Stomach, intestines, and appendix normal. The liver was yellowish red, and showed large areas of a lighter yellow, giving it a mottled appearance. The spleen was slightly enlarged. On section, the pulp was slightly exaggerated. The pancreas was normal. The cortex of the kidneys was smooth, grayish yellow; slightly dull and intralobular vessels markedly injected. The bladder was contracted and empty. The entire mucous surface showed a hemorrhagic cystitis. The uterus, tubes and ovaries were normal. Sections were taken from the bladder, spleen, liver, heart muscle and brain. The final report was encephalitis lethargica.

CASE IX.—M. G., aged forty-five, colored, married. Admitted March 6th, complaining of headache and pain throughout body. Patient later became drowsy and fell into a lethargic state. Had ptosis of both eyelids and slight rigidity of the muscles of the neck. The Kernig was positive; Babinski and Brudzinsky negative. Spinal puncture performed and twenty c. c. of clear, colorless fluid under moderate pressure withdrawn. The laboratory findings were twenty cells to the c. mm., Noguchi positive, Fehling positive, no organism was found. The blood showed, white blood corpuscles, 14,400, polynuclears 76 per cent., lymphocytes 24 per cent. The temperature was 100°-102°, pulse 100-124, respiration 30-40. The urine was negative, blood pressure was 122/100. The patient is still in the hospital convalescing.

CASE X.—One of the most interesting cases we had was that of J. L., aged thirty, white, Italian. Admitted February 22nd, with chief complaint of headache. Headache lasted seven days, and then the patient became drowsy; had pain in legs, and then became semiconscious.

Physical examination revealed a well developed and nourished young Italian, semiconscious, answering questions intelligently. When roused from his lethargy, having a sense of euphoria and manifesting twitching of arms, fingers, eyelids, and occasionally of the face, ptosis of both eyelids; no ocular paresis, knee jerks exaggerated bilaterally, no definite Kernig, positive Babinski, no ankle clonus. Spinal puncture was done February 23rd. The specimen was contaminated with blood and came under slight pressure.

The laboratory findings were, Fehling positive, Noguchi positive, and the sediment showed encap-

sulated diplococci resembling pneumococci. A diagnosis of pneumococcic meningitis was made with the feeling that the organism demonstrated was merely a contamination.

February 28th, lumbar puncture was done, ten c. c. of the fluid slightly contaminated with blood was removed under slight pressure and eight c. c. of patient's own serum injected intraspinally. The specimen showed, Fehling positive, Noguchi positive. No organism was demonstrated this time and the sediment culture was also negative, so we changed our diagnosis to encephalitis lethargica.

In looking over the literature on this subject, I find that no one adequately explains the cause of the lethargy seen in this disease. I beg to offer the following explanation and invite your opinions on this matter. In disorders of the hypophysis we find that lethargy is a very important symptom, and by administering the extract of the anterior lobe of the gland we can at times cure a case of lethargy due to hypopituitism. Now since the pathology of encephalitis lethargica shows a perivascular infiltration of the pons and medulla, I feel that by virtue of its anatomical relationship to the hypophysis by means of the infundibuliform process, it is rational to theorize that the lethargy is due to a hypopituitism resulting from the pathological condition extending to it.

The early occurrence of lethargy points to its being a focal symptom rather than an expression of intoxication of the higher brain centres. In otherwise mild cases with good complexion and clear tongue the lethargy may be well marked. In other words the lethargy bears no relation to the amount of infection. Hence, it is safe to assume that the lethargy sets in just as soon as the hypophysis becomes involved.

SUMMARY

In summarizing I wish to state that while the literature reports that the disease is more common in males than in females, our experience has been otherwise. Of our eleven cases, there were seven females and four males. Five of the female patients died—(three were pregnant). Out of the four male cases, one patient died and three recovered, which bears out the experience that the disease is more fatal to females. All of our cases may be classified as encephalitis lethargica. The onset was always insidious, with headache, malaise, weakness, vertigo, sore throat, diplopia and fever as common symptoms. Drowsiness occurred in almost every case, frequently developing into coma, and at times alternating with irritability and anxiety. Long projection fibre tracts to the arms and legs showed disturbances in some of our cases as indicated by spasticities, and Babinsky reflexes. The symptoms and signs referable to the brain stem were found in all our cases, together with oculomotor palsy. Weakness of the facial muscles was also characteristic. The pathology and symptomatology in our series corresponded very closely to that described by the men abroad and here. As to the etiology of lethargy I offer in explanation disturbances of the pituitary body due to the extension of pathological condition from the pons and medulla by means of the infundibuliform process which extends from the base of the brain to the hypophysis.

ENCEPHALITIS LETHARGICA IN FRANCE AND SWITZERLAND.

BY CHARLES GREENE CUMSTON, M. D.,
Geneva, Switzerland.

The clinical aspect of this morbid process since cases have become more numerous may, perchance, cause its name to be changed, but until we possess more information concerning it, I think the term encephalitis lethargica may be retained, although it is not quite correct, because most of the press communications have been printed under this heading. The history of this morbid process is, up to date, rather brief. It was observed by Camerarius and also by Sydenham, while in 1889-1890 the Italians referred to it by the name of nona, but it was von Economo, of Vienna, who, with other workers, described the disease in 1916-1917. In 1918 the disease appeared in England and France, and after a period of quiescence, it again developed in Italy, France and Switzerland, where cases have become more numerous ever since. First encountered in the Parisian suburbs, it extended over vast territories, especially Alsace, Cherbourg, in the Loire and Bordeaux. Nearly all the Swiss cities have been affected by it and at Geneva to date we have had more than twenty-two cases, which is a fair number for a city of one hundred and forty thousand.

It may be assumed to be an infectious disease, its morbid agent as yet unknown and producing lesions preferably in the mesocephalon. The symptomatology is regarded as being represented by three principal phenomena, namely, fever, paralysis of the third cranial nerve, and somnolence, but, as I shall show, this is subject to revision. The prognosis is variable and treatment uncertain. Although moderately contagious the disease is unquestionably transmissible by the intermediary of the bucconasopharyngeal mucus, a transmission similar to that of influenza, and it is remarkable that epidemics of the latter affection appear coincidentally with the appearance of encephalitis lethargica.

The symptomatology as encountered in France has been well described by Netter. The disease is usually febrile, commencing with headache and occasionally vomiting. Somnolence rapidly supervenes and becomes progressively accentuated. At first there is drowsiness only and this is followed by a true sleep from which the patient can be aroused, will reply to questions, and walk about, but as soon as he is left alone he will relapse into sleep. At a more advanced phase sleep may be interrupted by delirium, tremor, and exceptionally convulsions. Usually, however, there is only sleep. The muscular system of the eyes is almost always involved—paralysis of eyelids, nystagmus and rarely diplopia. Somnolence, headache, and ocular disturbances naturally lead one to suspect meningitis, simple, cerebrospinal or tuberculous. However, the ordinary signs of meningitis are wanting or only slightly marked. The meningeal line can be readily provoked and although pressure of the globes is painful, irregularity of both pulse and respiration is generally absent. Stiffness of the neck and Kernig's sign are slight or absent. Lumbar puncture gives a clear fluid containing a normal percentage of albumin and from two to three cell elements, rarely as many as seven. Cultures of

the cerebrospinal fluid remain negative. Therefore, if the physician is not on his guard, a diagnosis of cerebral tumor and especially tuberculosis of the cerebellum will be made. If the affection is prolonged and the subject recovers, such a presumption might seem justified, but if death ensues no trace of tubercle will be found. Both the surface and sections of the brain appear normal or simply injected with a diminished consistency. The evolution of the process is variable. Some subjects die within a few hours of the onset, others as late as the seventeenth day. Some recover in a few days, others after several weeks.

This describes the type of encephalitis lethargica most frequently observed, but the significance of the symptoms presented should be given careful consideration. Let us consider the three principal symptoms separately.

The fever denotes an infection of the organism but it is irregular in the intensity of its manifestations. In a large number of cases the temperature remains in the neighborhood of 100.5° to 101.5° F. In others it goes to 102°, 103° or even 104° F., and it seems now logical to assume that the height of the temperature is in direct relation to the gravity of the infection. There are instances where no thermic rise has been observed. When there is fever the morning remission is sometimes very trifling.

The fever is accompanied in most cases, and occasionally preceded by, other evidences of infection, among which slight chills, an increased pulse rate, vomiting and coated tongue are to be noted. It is usually these symptoms with a rise in temperature that mark the onset of the disease but at the same time they appear the patient will complain of headache. This clinical picture is quite constant and those patients too sleepy to reply to questions keep their hands on their foreheads thus indicating cephalalgia.

The somnolence which is present has given its name to the affection and it would consequently seem that it exists in all cases, but instances are reported in which it was absent. However, it may be regarded as one of the most constant symptoms. It varies greatly in degree, duration and time of appearance, but it should be regarded as one of the earliest signs and when the general symptoms are not marked it is the first one to be manifested. Therefore, in those cases where the diagnosis has been made from somnolence alone it will probably be correct in the majority of instances.

In a large proportion of cases the somnolence is continuous, the subject appearing like one in ordinary sleep. If he is called or an attempt made to arouse him from his stupor he will awake, but if left alone sleep returns. When the subject replies to questions he does so in the weary way of a person who wants to sleep. In other cases the somnolence is less profound, the patients having the look of one merely tired and attempting to do no more than possible. In reality, they are fighting against sleep—and some subjects resist it to such a degree that they try to get up and be about in order to overcome the somnolence.

If they accomplish their end they stagger about and, obliged to give up, fall into a state of lethargy.

Patients in hospitals have been known to get up, make their beds and then fall asleep. Finally, certain patients present a true narcolepsia, more like coma than ordinary sleep. The muscular system is absolutely relaxed, the eyelids remain closed, and if they are raised the pupils will be found turned upward as in normal sleep. This fact has been referred to by F. Lévy, who has also observed an incontinence of urine and feces in complete coma. The duration of the somnolence is variable, lasting from a few hours only to several weeks if not months. It frequently continues after the disappearance of the general symptoms, especially the rise in temperature.

In the earlier descriptions of the ocular phenomena of encephalitis lethargica, the paralysis was said to involve almost exclusively the motor muscles of the eye, but of late they have been singularly increased and they are unquestionably very valuable diagnostic signs. Morax and Pollack have given particular attention to their study. These observers have pointed out the integrity of the sensory and sensitive functions of the visual apparatus to which is opposed an intrinsic or extrinsic involvement of the motor apparatus of the ocular globe. Bilateral incomplete ptosis is an almost constant symptom, although sometimes quite fleeting. Strabismus is less constant and generally convergent, appears at the onset of the disease, and quickly disappears. Diplopia is variable, often atypical and should be looked for in extreme movements. There is an almost constant presence of disturbances of the associated movements, especially the vertical. These disturbances are to be opposed to the rarity of a limited involvement of one oculomotor nerve.

The frequency of unequal pupils and the constancy of paralysis of accommodation should also be noted. It is common to observe that some of the ocular signs, particularly nystagmiform disturbances in the movement of elevation, persist after the clinical recovery from the disease, or at least subside very slowly. But the paralyzes are not confined to the muscles of the eye and other nerves originating in the mesocephalon may be involved, such as the common oculomotor, facial, hypoglossus, glossopharyngeal and pneumogastric. Facial paralysis has been especially observed and Sinton had a case of complete immobility of the expression.

It may be proper here to refer to paralyzes met with in the territories of entirely different nerves, such as fleeting paralysis of the limbs, epileptiform convulsions reported by Khoury and Chauffard, clonic movements referred to by Halbron, and sudoral paroxysms mentioned by Khoury.

Among accessory symptoms may be mentioned asthenia which, although almost constant, may, when existing alone, be regarded as an outcome of somnolence. Retention of urine has been mentioned by Halbron, Souques, and Lereboullet, multiple neuralgia by Netter, Salmont and Léry, rather durable confusional states by Claude, tremors and exaggerated reflexes by Lhermitte and Babinski's sign.

The evolution of encephalitis lethargica is extremely variable. There are subacute cases with a small thermic rise or even none whatsoever, where all the symptoms are little marked and result in rapid re-

covery. There are hyperacute forms ending in death in a few days. The ordinary acute types end in death by a progressive aggravation of the symptoms or, on the contrary, by a remission of the symptoms announcing a favorable issue, although this may take several months. The prolonged cases reported by Netter and Sinton, where it took two, three or more months for recovery to take place, were particularly numerous in the Vienna epidemic of 1917. Chauffard and others have described ambulatory forms which did not prevent the subject from continuing his ordinary duties, but Lortat-Jacob states that in them there was diplegia, nystagmus and a perpetual tendency to sleep. Sicard and Kudelski have described types particularly distinct from the typical cases, which they propose to call acute myoclonic encephalitis, characterized at the onset by lancinating pain, moderate fever and headache, while in the phase of full development short, rapid, explosive muscular jerkings are noted—having the electrical rhythm—located in the muscles of the limbs, face, and diaphragm or localized to a section of the body, sometimes with a tendency to generalize. There are no ocular symptoms or somnolence. Then delirium appears, usually the oneiric type, and coma supervenes, although the jerkings continue. These observers have also described relapsing forms in which the patient, rather seriously ill, presented a remission for a couple of weeks during which he returned to work and then relapsed for several months.

Achard, of Paris, and Cramer and Koch, of Geneva, have referred to the clinical diversity of this morbid process. The modalities of the intensity of the somnolence, the symptoms of excitement replace those of depression, etc., so that we must conclude that the disease is both polymorphous and acyclical. The Paris and Geneva observers have shown that the microscopic lesions are seated in the cerebral cortex and especially the ganglia, in the protuberance and bulb. The vessels are surrounded by cuffs of cells particularly in the gray matter of the third ventricle, the aqueduct of Sylvius and in the nuclei of the motor nerves of the eye. The nerve cells undergo morbid changes. From the quite considerable number of autopsies made to date it is evident that the lesions of encephalitis lethargica are seated in the mesocephalon surrounding the ventricles and are microscopically of little import, the conjunctivovascular changes being the most marked. Netter and others who just described this disease maintained that the cerebrospinal fluid was normal but we now know that such is not the case and that a mild lymphocytosis is common in the advanced phases of the affection and even a marked one may be found, but the percentage of albumin remains normal. Let me add that there are still some observers who are in doubt on the subject of lymphocytosis so that more work along these lines must be forthcoming before any exact conclusion can be reached.

Of the diagnosis and prognosis of encephalitis lethargica it is quite unnecessary for me to speak, likewise of treatment which is still a matter of study, but in conclusion I would briefly refer to the nature of this interesting morbid process. I have considered encephalitis lethargica so far as a perfectly distinct

affection due to an infectious agent belonging to the class of filterable virus and as yet unidentified. This is the opinion of most observers on the continent but in this respect opinion is not uniform and perhaps it is not devoid of interest to refer to this aspect of encephalitis lethargica.

In 1917, Cruchet described a diffuse encephalomyelitis which assumed divers clinical forms: mental, convulsive, choreic, meningitic, pontocerebellar, bulboprotuberantial, etc., and he believed that encephalitis lethargica was one of the types of this encephalomyelitis. Lhermitte and some others maintain that encephalitis lethargica is simply a syndrome, the expression of an infectious process in the mesocephalon. Page recalls that Sinton's cases seem to be related to an influenzal infection, that one of Lortat-Jacob's was related to syphilis, and that Lesage and Abrami have described a somnolent type of tuberculous meningitis. Comparing these facts with two cases of his own in which the encephalitis lethargica was merely an episode in the evolution of tuberculosis, Page believes that several toxins—one being that of tuberculosis—are susceptible of adulterating the hypnic centre which appears to be located in the mesocephalon and whose involvement, although temporary, produces the syndrome of encephalitis lethargica.

What is more important, however, as Cruchet has pointed out, is the cause of this involvement of the nervous centres. Netter, who sees an unquestionable analogy between encephalitis lethargica and poliomyelitis, maintains that the former is a specific morbid process with a well defined virus of its own and he opposes the opinion which has been expressed upon several occasions that the disease under consideration occurs with epidemics of influenza and assumes that the former process is due to influenzal virus or some associated microbe, such as those giving rise to influenzal pneumonia. This opinion is also opposed by Cruchet and Claude, the latter observer pointing to the fact that the cause may not be universal. All this is to come back to the conception of an encephalitis syndrome that several toxins may be capable of producing.

INTRAVENOUS AND INTRASPINOUS TREATMENT OF MENINGOCOCCUS MENINGITIS.*

By DAVID GOLDBLATT, M. D.,
New York.

The one outstanding contribution to the study of meningococcus meningitis during the past two years is the conception of the infection as a generalized one primarily, with secondary localization in the meninges. The disease had previously been studied carefully by Flexner and his associates at the Rockefeller Institute, and they have demonstrated that the infection was the result of direct transmission of the organism into the meninges by way of the cribriform plate of the ethmoid.

But it was mainly through the work of Herrick and his associates at Camp Jackson, where many cases of meningitis have been studied, that we came

*Read before the Harlem Hospital Clinical Society.

to recognize the disease as a generalized infection. Workers at other camps and especially Haden, at Camp Lee, have confirmed this view. Of course it had been long known that there was a type of the disease, fulminating in character, in which the infection was evidently generalized. But it had been held by most observers that the majority of cases were primarily a localization from the outset.

Coupled with the conception of the disease as a generalized one there have been new ideas brought forward for treatment. It has been shown that intravenous therapy markedly influences the course of the disease. This result is well illustrated in the Camp Jackson series, where with intraspinal treatment alone the mortality was 34.3 per cent., and in the combined intravenous and intraspinal treatment the mortality was 14.8 per cent. Herrick also emphasizes that it is in the more severe cases that the newer method is more effectual. Intravenous therapy also decreases the number of intraspinal treatments, and the harmful results from continued intraspinal treatment have not been sufficiently emphasized.

The majority of bad sequellæ following intraspinal treatment are due to a myelitis of the cauda equina, the direct result of trauma incidental to a lumbar puncture and the introduction of serum intraspinaly; and these explain the pain and stiffness of the back and legs. Rosanoff from a study of twenty-six cases, describes what he calls a uniform postmeningitic syndrome.

Objection has been raised to the intravenous treatment by several workers, especially by Neal, who states that intravenous therapy neutralizes the toxins and destroys the organisms circulating in the blood stream, and since the ability of the choroidal plexus in filtering through antibodies is still questionable, it would not influence the localized condition. But, I believe, we are justified in assuming that by destroying the organisms in the blood stream and meninges by the combined therapy, we preclude the possibility of a reinfection, which is not as uncommon as one would think. Herrick reports seven cases of reinfection occurring within several weeks or months of the primary infection.

Prompted by the good results obtained at the army camps, we decided to try the combined treatment at the Harlem Hospital and prove for ourselves the value of it. We cite the following case in confirmation and corroboration of the treatment outlined above:

CASE.—Patient A. S. D., aged eighteen, female, was brought into the hospital February 15, 1920, complaining of headache, pain in the back of the neck, and fever of two days' duration. Her mother and father were well and living in Porto Rico, her native land. She had no infectious diseases during childhood or thereafter, and no operations. The menstrual cycle first appeared at twelve, being of the monthly type and flowing for two or three days. She had been married for two years and had no children or miscarriages. Venereal diseases were denied by name and symptoms. Her habits were irrelevant. Her present illness dated back to three weeks prior to admission to the hospital, when she experienced a chill which wakened her from

sleep and lasted for about half an hour. Following this she was delirious for several hours, and remained in bed for a week, at the end of which time she felt well enough to go to work. This she did for about a week. At the end of this time, while at work, she experienced a sudden severe headache, vomited and was feverish. She immediately went home where she remained for two days until her admission to the hospital. The pain in the head persisted, and associated with it were pains in the back of the neck and upper part of the back. There was no history of cough, expectorations, sweats, or hemoptysis.

The physical examination revealed a well developed and well nourished, apathetic, young white woman, appearing acutely ill, and apparently unconcerned about what was going on about her.

Temperature, 105°; pulse, 116; respiration, 24. On touching the neck or upper portion of the back she complained of pain. The skin was soft, warm, moist and free from rashes. The examination of the head and eyes were negative, with the exception of weakness of the right internal rectus. The breath had a foul odor, the lips were dry and crusted, the tongue was coated with white fur, and the throat was injected. The neck was markedly rigid, there being limitation of motion from side to side as well as from before backward. The examination of the chest, lungs and heart proved negative; the pulses were equal, full and bounding, but rapid. Blood pressure, 120-70. The abdominal findings were negative, with the exception of slight tenderness in the hypogastrium; the liver and spleen were not enlarged; the kidneys were not palpable. The superficial lymph glands were not enlarged. The knee jerks were equal, very active, and no Babinski or its modifications could be elicited. Brudzinsky's and Kernig's signs were both strongly positive.

The urine was negative with the exception of a few red and white blood cells. The white blood count was 12,400, with 78 per cent. polynuclears and 22 per cent. lymphocytes. The blood culture was negative on two occasions. The spinal fluid was cloudy, and under pressure had 850 cells to the c. c. with 61 per cent. polynuclears and 39 per cent. lymphocytes. The Noguchi test was positive and the Fehling test negative. No organism was demonstrated in this first examination. Subsequent spinal fluid examinations showed a variation of total cell count from 500 to 1100 cells to the c. c., with 75 per cent. to 99 per cent. polynuclears.

On February 25th a gram negative intracellular diplococcus, having many of the morphological characteristics of the meningococcus, was demonstrated. This was the sixth spinal puncture.

Reviewing the history and bearing in mind the mode of inception of the disease in this case, I believe we can rightly assume, that the condition apparently began as a generalized infection which was rather mild, not prostrating the patient, but later localizing in the meninges and there manifesting its virulence. The interval of apparent freedom from symptoms as demonstrated in this case has been vividly brought to notice by many of the cases in the army, where soldiers were ill and incapacitated for

several days, to return to duty at the end of this time, and two to three weeks later be readmitted with frank manifestations of a meningitis.

Considering the case as one of meningococcus meningitis, although the first spinal fluid examination did not show the organism, treatment was instituted as follows:

The patient was first tested for sensitization to horse serum and at the end of a half hour, the reaction being negative, 100 c. c. of antimeningococcus serum were given intravenously. This was followed eight hours later by a lumbar puncture with the injection of fifteen c. c. of serum intraspinally. Twenty-four hours after the first intravenous injection, 100 c. c. were again administered intravenously. Twenty-four hours later ten c. c. of serum were given intraspinally. Thus intravenous and intraspinal treatments were alternated for four doses, at time intervals ranging from eight to twenty-four hours, and the temperature coming down to 100° F., the patient was left alone to see what would happen. At the end of this free from treatment interval the temperature rose to 103.5° F., and an intraspinal treatment of twenty-five c. c. was given. The next day the temperature dropped, but within twenty-four hours rose again and assumed a definitely septic character for three days. During these three days intraspinal treatment alone were used to see the effect of this treatment. We now decided upon an energetic intravenous treatment alone, to see what effect this route of treatment would have upon the disease. For four days a daily injection of serum was given intravenously, beginning with eighty c. c. the first day and sixty c. c. every following day. At the end of this treatment the temperature came down to 100° F., and did not go any higher for six days. On the seventh day a lumbar puncture was made and the fluid was reported as being almost normal, there still being a slightly positive Noguchi. On this day following the intraspinal administration of serum, a routine after each spinal puncture, the temperature rose to 102.5° F., and came back to normal within twenty-four hours. I believe this rise in temperature was due to a partial injection of the serum into the connective tissue between the dura and the bone, as the patient complained of pain during the administration.

In closing I would like to emphasize the salient features of this treatment and although I am aware that one case is not sufficient to draw conclusions from, I cannot help being impressed by the marked improvement in this patient after energetic intravenous therapy.

CONCLUSIONS.

1. Intravenous therapy combined with intraspinal treatment, aims at a rapid sterilization of the blood and meninges and thus shortens the period of morbidity.

2. Intravenous therapy reduces the required number of intraspinal treatments, and if started early may abort the disease.

3. With a moderate amount of care the intravenous therapy is free from danger and should be used in cases that clinically indicate a severe type of the disease.

AN EPIDEMIC OF TYPHOID FEVER OF WATER BORNE ORIGIN AND CARRIER TRANSMISSION.

At Camp Hospital No. 10, Prauthoy, Haute Marne, American Expeditionary Forces, France.

BY LEON H. CORNWALL, M. D.,
New York,

Pathological Laboratories, City Hospital, Blackwell's Island;
Captain, Medical Corps, U. S. Army,

AND JAMES P. CRAWFORD, M. D.,
San Francisco,

Captain, Medical Corps, U. S. Army.

(Continued from page 150)

CARRIERS.

CASE I. (19) Private Battery E, 320 F. A. Admitted February 9, 1919, as a result of the isolation of *Bacillus typhosus* from the feces during the search for carriers. He had been on kitchen police since December 18, 1918. On February 6th this man had a temperature of 100.2°. For three days following it was normal. On February 10th it was again 100.2° but normal for the succeeding five days. On the 16th it was 101.6° and on the 17th 99.6°. There was no fever after that. All subsequent laboratory examinations were negative except for the presence of diazo bodies in the urine on the seventeenth day. The typhoid complement fixation was positive but the agglutination titre of the serum was not high. Inoculated with U. S. triple typhoid vaccine October 15, 1917, and with French triple typhoid lipovaccine January 31, 1919. It is an open question if this was not a case of mild typhoid.

CASE II.—(20) Cook Battery E, 321 F. A. Admitted February 12, 1919 as a result of the isolation of *Bacillus typhosus* from the feces during the search for carriers. He was kept under observation for over a month during which time there were eight negative feces examinations. There was a positive complement fixation and the agglutination titre of the serum was moderately high. Inoculated with U. S. triple typhoid vaccine January 3, 1918, and with French triple typhoid lipovaccine January 31, 1919.

SUSPECTED CLINICAL CASES.

CASE I.—(21) Private, Battery E, 321 F. A. Admitted February 23, 1919, complaining of slight bronchitis, headache, pains in back and legs, weakness and poor appetite. Onset February 22, 1919. A palpable spleen was noted on the day after admission. Epistaxis occurred at the same time. Headache was complained of on the fourth and sixth days. The temperature ranged from 99° to 101° for seven days. The pulse averaged 80 and the respiration 20. There were no laboratory findings upon which could be based a positive diagnosis of typhoid fever. Four blood cultures, five fecal cultures and three urine cultures were negative. There was a positive complement fixation and only a moderately high agglutination titre for the serum. Inoculated with U. S. triple typhoid vaccine October 11, 1917 and with the French triple typhoid lipovaccine January 31, 1919.

CASE II.—(22) Private, Battery E, 321 F. A. Ad-

mitted February 26, 1919, complaining of slight bronchitis, chilly sensations, headache and meteorism. Onset recorded as February 24, 1919. On January 28th, 29th and 30th and February 5th, 6th and 7th this man reported at sick call with practically the same group of symptoms as those complained of on admission but there was no rise in temperature at any of these times. He had been on kitchen police since January 1, 1919. During the interval between January 28th and February 26th he performed full duty. He had a rise in temperature for four days as follows: February 26th, 100.5°, February 27th 99.6°, February 28th and March 1st, 101.6°. There were no other clinical symptoms of typhoid fever. Blood, feces and urine were negative bacteriologically. The diazo reaction was positive in the urine on the second day after admission. The complement fixation was positive and the agglutination titre of the serum was sufficiently high to be very significant. Inoculated with French triple typhoid lipovaccine January 31, 1919.

On the evening of January 26th a patient was admitted to Camp Hospital No. 10 from Battery E, 321st Field Artillery with a temperature of 100.6°, pulse of 90 and respiration of 16. He gave a history of acute generalized abdominal pain, which began on the previous day, but stated that he had been tired and had felt weak for three or four days. The admission diagnosis was acute appendicitis and he was immediately evacuated to Base Hospital No. 53 at Langres. The diagnosis was confirmed there and an appendectomy was performed that evening. The appendix was described as being postcecal with adhesions. It was acutely inflamed and had ruptured. There was free fluid in the abdominal cavity and pus in the right iliac fossa. For the first few days after the operation there was some abdominal distention, pain and vomiting, and the temperature remained around 102°, pulse 80 to 116, and respiration 20 to 24. In the patient there developed an apathetic state suggestive of typhoid but there were no rose spots, splenic enlargement nor diarrhea. The leucocyte count averaged 6,500 with forty per cent. lymphocytes. Blood, feces and urine cultures were made at the laboratory of Base Hospital No. 53 but were all negative for the *Bacillus typhosus* and *paratyphosus*. The temperature and general condition of the patient remained approximately the same until the fifth week, when the temperature dropped to normal by lysis.

During convalescence this patient admitted having drunk unchlorinated water at Rosoy. His service record was not available but he states that he had been inoculated six times before leaving the United States. It is probable that this was another case of typhoid and that it belonged to Group 1. This record was not available at the time that the cases were being studied at Camp Hospital No. 10, hence it was not included in the tabulations. The data concerning this case were placed at our disposal through the courtesy of Major C. E. S. Webster, M. C.

CLINICAL OBSERVATIONS.

Onset.—In approximately sixty per cent. of the cases the onset was gradual and more or less insidious. Four men (Nos. 12, 14, 15 and 18) were

hospitalized as a result of taking the temperatures of all of the men in Battery E daily. They would not otherwise have been discovered so early. One of these men (No. 15), however, had rose spots, a palpable spleen and a temperature of 102° on admission. Despite the fact that his temperature continued high he denied malaise until the eleventh day. Careful interrogation of the patients after their arrival at the hospital, for the purpose of ascertaining the earliest subjective symptoms elicited the information recorded in Table II, as follows:

TABLE III.

	No.	Percentage.
Headache	11	61
Fever	9	50
Malaise	7	39
Anorexia	7	39
Bronchitis	5	28
Constipation	4	22
Chilly sensations	4	22
Pains in back	4	22
Pains in legs	4	22
Generalized pains	4	22
Vomiting	2	11
Epistaxis	2	11
Abdominal discomfort	1	5.5
Diarrhea	1	5.5
Vertigo	0	0
Pain in right iliac fossa	0	0

When the epidemic originated the intervals between the onset and hospitalization were quite long. These intervals varied from three to twelve days in the first group. With the exception of one case (No. 15) the others were admitted before the sixth day. This was due, in large measure, to the search for febrile cases. It serves to emphasize the difficulty of early diagnosis of typhoid, in persons who have been inoculated, by attention to subjective symptoms alone. Several men, during the first few days of their illness, could not be convinced that they were sick enough to be kept in the hospital

DIAGNOSIS.

Fever was the most constant early objective symptom, all of the patients having some hyperpyrexia. It was extremely irregular, however, and to be appreciated required that it be taken and charted at frequent intervals.

Headache was a pretty constant early complaint (sixty-one per cent.) and was present at some time in sixty-six per cent. of the patients.

Bronchitis, though not especially prominent as an early complaint, was noted on physical examination before the third day in thirty-nine per cent. and at some period of the illness in sixty-six per cent. of the cases.

Anorexia was only noted as an early complaint in thirty-nine per cent. and in only forty-four per cent. of all cases during the illness.

Malaise was complained of early in thirty-nine per cent. but during the illness only fifty per cent. acknowledged that they had it.

Constipation was not prominent, being noted in only four cases.

Early diarrhea, persisting from the second to the seventeenth day was present in one case. Another man had diarrhea from the third to the fifth day and one had it for four days in the fourth week. As an early symptom of diagnostic value, therefore, it was noted only once in this series.

Pains in back, pains in legs, and generalized pains were each noted four times but abdominal pain was infrequent, never prominent as a nearly symptom,

and only severe in two cases, one of which perforated. Right iliac pain was never noted.

Epistaxis was present twice in the first week and twice in the second (twenty-two per cent.) of the cases.

Vomiting occurred three times in the first week and whereas it occurred in three other cases in the third or fourth week, it was never persistent or troublesome. Total incidence thirty-three per cent.

Among the objective findings rose spots were the most constant, being present in fifteen cases (eighty-three per cent.); six times in the first week; four times in the second; three times in the third; once in the fourth; and once in the fifth.

A palpable spleen was recorded twelve times (sixty-six per cent.); three times in the first week; five times in the second; three times in the third; and once in the fifth.

Meteorism was noted five times (twenty-eight per cent.) in the first week and at some period of the illness ten times (fifty-six per cent.)

Delirium occurred but once before the fourth week. Four patients (twenty-two per cent.) were delirious at some time.

Jaundice was present only in one case.

COMPLICATIONS.

Bronchopneumonia was noted clinically four times (Nos. 1, 3, 4, 15), and was discovered at autopsy in two other cases. It was not present until the third week. Lobar pneumonia was diagnosed once clinically and was confirmed by autopsy.

Intestinal hemorrhage occurred in three cases (Nos. 1, 5, 12). It caused complete exsanguination and was the immediate cause of death in one case (No. 5). In the other two cases the intestinal hemorrhage was not in itself, the cause of death. It was a contributing factor in No. 1 and incidental in No. 12, death being due in the latter, to perforation followed by general peritonitis.

Nephritis was present in two cases (Nos. 1 and 16). In the former it was a contributing factor in producing death but the latter case recovered. It is worthy of notice that the *Bacillus typhosus* was only isolated from the urine of this one case (No. 16).

Phlebitis of the left leg occurred in one case (No. 13), acute catarrhal otitis media once (No. 8) and perforation once (No. 12).

RELAPSES.

In only two cases was the clinical course suggestive of a relapse. In No. 7 the temperature ranged from 102° to 104.6° for six days, then fell by lysis reaching normal on the eleventh day after admission. After remaining normal for twenty-four hours it gradually ascended to 104° and ranged between that point and 101° for twelve days, when it fell to normal by crisis. In case No. 16 the temperature was 104° on admission. It gradually fell by lysis, reaching normal the fifth day after admission. It remained normal for twenty-four hours, then ranged from normal to 99.6° for three days, then rose to 102.4°. It remained between 102° and 103° for five days and then fell by lysis, again reaching normal on the twenty-second day after admission.

DURATION.

The shortest duration was eleven days, the longest forty-seven days, and the average twenty-nine days.

TERMINATION.

Death terminated six cases. Five of the deaths occurred in the first group of seven cases, which, there is reason to believe, received the most massive infections. Three of the patients were hospitalized in the first week, two in the second, and one in the third. There were twelve recoveries; one by crisis, two by rapid lysis, and nine by the usual lysis.

PATHOLOGICAL ANATOMY.

An opportunity was afforded to study the gross pathology in six cases and several features were noted that deserve attention because of the possible relationship between antityphoid inoculation and the pathological anatomy that was observed.

Intestinal lesions.—In every case that was autopsied there were, in the upper intestines, lesions having the typical shaven beard appearance of healed typhoid ulcers. These lesions extended rather high in the duodenum, in two cases being noted within six inches of the pyloric opening of the stomach. One case showed a very acute duodenitis of the upper twelve inches of the duodenum. The mucous surface of the gut was roughly granular due to the hyperplasia of the lymphatic tissue in the submucosa. There was an intense congestion of the blood vessels of the mucosa and submucosa giving to the gut, a bright red color. With regularity the lesions became more extensive and severe as one proceeded with the examination of the intestines from the upper to the lower portions. First one would encounter in the lower duodenum or upper jejunum sometimes right at the side of a healed lesion, a round or oval swollen avascular lymphatic patch; then an acutely inflamed, bright red, swollen patch; then a similar patch with a small central excavation; and then still lower down, usually in the lower ileum or ileocecal region, the typical large, deep, round or oval ulcerations, extending through the mucosa, submucosa and musculature. The ulcerations extended into the colon in three instances; once in the ascending; once in the ascending and transverse; and once in the ascending, transverse and descending. In one case (No. 2) the intestinal lesions were all either healed or rapidly healing. Death was due to an intercurrent lobar pneumonia.

Pancreas.—The pancreas, in every case that was autopsied was very firm and grossly suggestive of an interstitial pancreatitis. Microscopically those examined showed a cellular infiltration and fibrous tissue proliferation between the glandular acini and in the interlobular tissue. This indicates that the infection extended from the duodenum up through the pancreatic ducts, causing diffuse interstitial pancreatitis.

Gallbladder.—There was an acute catarrhal cholecystitis in five of the six cases.

Spleen and mesenteric lymphatics.—In no case was there more than moderate hyperplasia of the spleen, and the hyperplasia of the mesenteric lymph glands with the accompanying distension of the lymph channels seemed to parallel the splenic hyperplasia.

Kidneys.—Acute focal glomerulitis was noted once (No. 1). In no other case was there more than a moderate cloudy swelling of the kidneys.

Lungs.—Lobar pneumonia was present once (No. 2), very late terminal bronchopneumonia twice (Nos. 1 and 12), a generalized lobular pneumonia three times (Nos. 3, 4 and 5). Healed or chronic inactive pulmonary tuberculosis was noted in three cases (Nos. 4, 5 and 12).

CAUSES OF DEATH.

The immediate causes of death were as follows:

Lobular pneumonia, two cases; terminal bronchopneumonia and focal nephritis, one case; lobar pneumonia, one case; fatal hemorrhage, one case; perforation, one case.

LABORATORY EXAMINATIONS.

Technic.—Blood cultures were made by placing two to three c. c. of blood after puncture of the median basilic vein into fifteen c. c. of bile medium contained in a test tube. The use of small amounts was necessitated for the conservation of materials. These were incubated for eighteen to twenty-four hours and examined for the presence of typhoidlike organisms. Final identification was made by subcultures on endo medium, Russell's triple sugar and agglutination with diagnostic sera prepared at the Central Medical Laboratory, Dijon, France. Subcultures of all of the strains isolated were sent to the central laboratory for complete biological and immunological study.

Feces cultures were made by taking swabs directly from the stools and sending them to the laboratory in sterile test tubes. Fifteen c. c. of ordinary peptone broth medium was inoculated from the swabs and after standing for two hours at room temperature a drop of this broth was transferred to an end plate and smeared with a metal rod. A second end plate was made from the first. Subsequent subcultures were made as for blood. Urine was obtained in sterile test tubes and was added in the proportion of one to three to peptone broth and incubated eighteen to twenty-four hours. Examination was then made for organisms of the typhoid group. If present subcultures were made upon end medium and then regular routine. All original cultures from blood, feces and urine were incubated and subcultured for five successive days before the rendition of negative reports.

Agglutination reactions were done by a slightly modified Dreyer technic. The diagnostic sera were obtained from the central laboratory and the same sera were employed throughout. The following is the history of the diagnostic sera: Paratyphoid A (C. M. D. L. 399), prepared from culture of *Bacillus paratyphosus* A (New York Health Department strain 228 as antigen); paratyphoid B (C. M. D. L. 78), prepared from culture of *Bacillus paratyphosus* B (New York Health Department strain 225 as antigen). Typhoid (C. M. D. L. 429), prepared from culture of *Bacillus typhosus* (Mt. Sinai Hospital, New York city, strain 1 as antigen). The bacterial emulsions employed for the Widal reactions were obtained from the central medical department laboratory. The same batch of emulsions was used for all of the reactions.

The following is the history of the bacterial emulsions: Paratyphosus A prepared from New York Health Department strain 228; paratyphosus B prepared from New York Health Department strain 225. Typhosus prepared from Central Medical Department Laboratory strain 11, a Rawlings strain from the U. S. Army Medical School.

RESULTS.

The diagnosis of typhoid fever were confirmed by positive laboratory findings in seventeen of the eighteen clinical cases, ninety-four and one half per cent.

Blood.—Positive blood cultures were obtained in fourteen cases, seventy-eight per cent. The following data applies to the four cases in which positive blood cultures were not obtained: (No. 6) Admitted on the eleventh day of illness. The first blood culture was taken on the twenty-fourth day. The typhoid course was mild. (No. 11) Admitted on the third day of the illness. The original diagnosis was influenza but was changed to typhoid fever on the thirteenth day, after the isolation of typhoid bacilli from the feces. No blood culture was made. (No. 14) Admitted to the hospital on the third day of the illness. First blood culture was taken on the tenth day. No other confirmatory laboratory findings except a positive complement fixation. (No. 18) Admitted on the fifth day as a carrier after the isolation of typhoid bacilli from the feces. First blood culture made on the tenth day.

The earliest positive blood culture was obtained on the fifth day and the latest on the forty-third day. The diagnosis was first confirmed by blood cultures in nine cases, fifty per cent.

Feces.—Positive feces cultures were obtained in eleven cases, sixty-one per cent., the earliest on the second day and the latest on the twenty-ninth day. The diagnosis was first confirmed by the feces examination in seven cases, thirty-nine per cent.

Urine.—A positive urine culture was obtained from but one case, No. 16. The urinary findings gave evidence of nephritis on the third day of the illness. The diazo reaction was not significant enough to attach much importance to it. It was positive in two clinical cases, No. 12 and No. 15, on the twenty-fifth and sixteenth days respectively, in one carrier, No. 19, on the seventeenth day and in one suspected case, No. 22, on the third day.

Blood counts.—The lowest total leucocyte count was 4,200 on the twenty-seventh day and the highest was 10,800 on the fortieth day. Normal counts were the rule. The lymphocytes averaged thirty-seven per cent. The leucopenia ordinarily expected in typhoid cases was notable by its absence.

Complement fixation.—The complement fixation was positive in all of the cases.

Widal reactions.—Seven of the cases showed an increase of the agglutinin content of the sera from nine to over 4,500 units. No agglutination reactions were done on the sera of four cases and in four others but one estimation was made of the agglutinins. In one case the agglutinins remained constant and two cases showed a diminution after the first titration, indicating that the peak of the curve, or maximum agglutinin response had been reached and that the titration was again falling. The low-

est agglutinin content was nine units and the highest 9,000. The bacterial emulsions employed for the Widal reactions were standardized to a Dreyer emulsion, hence the tabulated results represent standard agglutinin units.

Had it not been our good fortune to obtain bacteriological confirmation of the clinical diagnoses in so large a proportion of the cases the agglutination reactions would have been of incalculable diagnostic value, and would have confirmed the clinical diagnoses in over fifty per cent. of the cases. The last five cases of clinical typhoid admitted to the hospital and the two carriers had been reinoculated with triple typhoid lipovaccine (French) on January 31, 1919, and this had to be considered in attaching importance to the agglutinin content of the sera. By comparing the results in these cases with two other series, one a group of men one month after inoculation with the same vaccine and the other a group who had not been recently inoculated, it will be seen that the relative values were as significant as in the other cases.

In its biological characteristics the strain of *Bacillus typhosus* isolated from this epidemic is not identical with the strain which is employed for the U. S. Army vaccine, differing in its fermentation reaction with xylose. From an immunological viewpoint this is of importance as it suggests these queries:

1. Are all strains of the *Bacillus typhosus*, which fulfill all of the requirements for an immunizing antigen equally efficient for protective inoculation?

2. Is a given strain, which fulfills all the requirements for an immunizing antigen, as efficient in producing immunity against another strain with slightly different biological characteristics, as an immunizing antigen homologous to the latter strain?

3. Should not the ideal immunizing antigen contain all strains that differ in their biological reactions? The immunological aspects of this problem will probably be the subject of later publications from the Army Medical School as it is now under extensive investigation.

CONCLUSIONS.

1. The probable source of this epidemic was polluted water.

2. It was further transmitted by carriers among food handlers.

3. The early diagnosis of typhoid fever among inoculated persons requires more attention to the objective than to the subjective symptoms.

4. Fever may be the only early objective symptom and may be present when no subjective symptoms are complained of.

5. Headache was the most constant early subjective symptom of this series of cases.

6. Malaise, anorexia and diarrhea were not prominent among the early symptoms in this series.

7. Antityphoid inoculation will not protect individuals against the ingestion of massive doses of typhoid bacilli.

8. The gross pathological anatomy of typhoid fever in inoculated persons shows some differences from that ordinarily observed. The intestinal lesions show evidence of a vigorous fight on the

part of the natural defenses of the body before succumbing to the infection. The extreme splenic hyperplasia ordinarily observed does not occur. Our experiences indicate that interstitial pancreatitis is a common result of typhoid infection in inoculated persons.

CHRONIC PERITONSILLAR ABSCESS.

By MAXWELL QUACKENBOS, M. D., M. R. C. S.
(Eng.)

New York.

The etiology of this comparatively rare lesion is obscure. Those textbooks which mention the condition voice the opinion that chronic peritonsillar abscess if encysted may be tuberculous in origin but attribute the malady most frequently to a caseous crypt of the tonsil. In many instances the abscess must be entirely overlooked, as for example when the operation of enucleation is performed by the digital method or the operative field concealed by hemorrhage with the swallowing reflex present. I do not see how the small pocket of pus can be possibly recognized and the diagnosis confirmed unless the deeply anesthetized supine patient's tonsils are enucleated by some dissection method as that of Waugh's technic, in which procedure a sandbag is placed under the shoulders and the head hyperextended so that the point of the chin, the neck and the chest are in a straight line. With the tongue drawn out by a suture through its dorsum and the chin held forward, this position gives an unobstructed view, a free air way and converts the nasopharynx into a dependent reservoir; no blood will then enter the larynx. In the six cases of chronic peritonsillar abscess herewith recorded the age incidence was between twelve and twenty-six years, four being female patients, three of whom gave history and showed evidence of tonsillotomy many months previously. All patients had suffered from the prevailing endemic of influenza. The symptom presented by the patients was the usual debility and its attendant secondary anemia. Two of the younger patients had superimposed renal symptoms of albuminuria. There was no history of throat trouble and no acute stage of inflammation. Enucleation of the small embedded tonsils was advised because of the palpable enlargement of the afferent cervical (tonsil) lymph node. The diagnosis of chronic peritonsillar abscess is dependent upon the observation of grayish pus of thick consistency in its cavity situation under the capsule in the region of the supratonsillar fossa. The largest abscess was the size of a split pea and all were located on the left side. The condition might be aptly described as an encysted abscess although the patients were not tuberculous. The abscess was not due to a crypt of the tonsil. There is no anatomical foundation for the belief that it arose as an adenitis of a lymph node in that region. I am of the opinion that this focal septic lesion is a sequella of constitutional infection (as empyema or an epiphysitis probably as a result of a bacterial embolus. Following enucleation the patient's condition rapidly returned to normal.

PHYSICIAN AND AUTHOR.

What has been described as "the most baffling bit of literature ever set down on paper" was written by Dr. Francois Rabelais—old Dr. Rabelais—upon whose head has been heaped more anathema than upon the head of any other writer. Those who are displeased with his coarse language and smutty yarns call him a filthy old blackguard, and will have none of him. On the other hand, Dr. Rabelais has his host of tolerant admirers throughout the world, and he has long been rated as a classic. The French have raised him to a pinnacle of fame, and unquestionably he was a humorist of the first rank, the father of ridicule, and merciless in flaying the customs of courts and convents, of schools and camps, of processes and wars, of romances and legends. The influence of Rabelais upon English literature has been greater than many persons would willingly admit; but the fact is that numerous authors studied and imitated him, as their work amply testifies. A shoal of minor humorists, poets and essayists have pillaged right and left from the stores of wit and humor in his *Gargantua and Pantagruel*, and English novelists have availed themselves of all sorts of plots and episodes from the same prolific source.

Rabelais was born about the year 1483 at Chinon, an ancient little town in the province of Touraine, France. The details of his life are enshrouded in uncertainty, but it is fairly definitely established that he spent at least twenty-five years in the cloister, first as a Franciscan monk, later as a Bene-

dictine, and finally gave up the cloistered life to enter Montpellier University, where he took all his degrees as a physician and gained a considerable reputation as a practitioner. During this practice he began writing medical tracts, and translated the Aphorisms of Hippocrates and some of the works of Galen, published first in 1532 by the famous Gryphius, of Lyons, and reprinted many times.

There is no clear record of how Rabelais came to leave Montpellier, but the supposition is that he probably was sent by the university to Paris to intercede for it at court, and was invited to remain at the capital, for he was a delightful fellow to have around. The generally accepted version is that, due to some mischievous pranks on the part of students, the university had been deprived of some of its privileges, and Rabelais so effectually pleaded the cause of the school that the chancellor immediately restored the privileges. Thus it is that, in gratefulness to the incorrigible old doctor, no one today is admitted to the degree of M. D. at Montpellier who has not first put on the cap and gown of Rabelais, which are preserved in the castle of Morac in that city.

Rabelais did not end his days as a physician. John, Cardinal du Bellay, Bishop of Paris, who had been Rabelais' friend from boyhood, employed him in a diplomatic position. It was at this period, some say, that he composed his *Gargantua and Pantagruel*. It seems to be fairly well established, however, that in addition to his practice as a physician at Montpellier he also served two years at Metz as the town physician, at the princely salary of one hundred and twenty livres a year. A livre was about twenty cents. And he also was physician for a time to the Hotel Dieu at Lyons, at the still lesser compensation of forty livres. They were generous to their physicians in those old days.

Rabelais' *Gargantua and Pantagruel* has been described as "a vast ocean of pure and impure tomfoolery and laughter surrounding a few solid islands of sense and reason and devotion." The greater part of these books is burlesque romance into which was introduced a vein of buffoonery quite in accordance with the spirit of the age. In it he delighted to make merry with the impertinences of mankind, and nothing was able to allay his mirth. It is wholly on this satirical work that the fame of Rabelais rests. His Latin versions of Hippocrates' Aphorisms and Galen are much esteemed also for their faithfulness and purity of style; but their circle of readers is small.

He also wrote several French and Latin epistles in excellent style to numerous great and learned men, and he wrote a book called *Sciomachia*, printed in Lyons in 1549. An Almanak for the year 1553, calculated by him for the meridian of Lyons, shows that he was an astronomer of great ability. Dr. Rabelais was also a poet, philosopher, grammarian and theologian, and a great linguist, skilled in French, German, Italian, Spanish, Greek and the Hebrew tongues, and his letters prove that he also understood Arabic, which he learned at Rome.

Rabelais died in a house in the street called La Rue des Jardins, in St. Paul's parish at Paris, about the year 1553, aged seventy years. But his fame will never die. The best pens of his age honored his memory with epitaphs, and since that time his name has appeared times without number in the literature of all lands. As he lived, so he died, jesting. Just before his demise he wrote a will, which, when opened, is said to have contained these three articles: "I owe much, I have nothing. I give the rest to the poor."

HOURS OF WORK AND HEALTH.

The relation of hours of work to fatigue concerns the preservers of health; the relation of hours of work to production concerns the managers of industry. Thus far most of the latter have gone ahead on the theory that the more hours the more production, without any great thought as to the effect on the individual workman. Now and then it was bruited abroad that such a policy involved an immense waste of human material, but this did not worry many people except those who were being wasted. Then the war came with its need for intensified production, leading to an unparalleled publicity campaign for physical fitness. Even workmen were included, for the truth came out that people cannot work too long and too hard without suffering.

England was one of the first countries to conduct scientific investigations into the question of fatigue and hours of work. England tried to speed up her munition workers until she discovered that they were breaking under the strain; then studies of the munition industry were made, with the result that hours of work were shortened and both the health and effectiveness of the workers were increased. Now comes our own Public Health Service with a report (*Public Health Bulletin* No. 106, *Studies in Industrial Physiology*) proving the superiority of the eight over the ten hour day. The findings are based on a comparison of an eight and a ten hour plant, each a huge industrial establish-

ment prominent in the metal working industry. Superiority of the eight hour day was proved from the economic standpoint—that is, in respect to maintenance of output, lost time, and labor turnover. But the eight hour day was also proved more beneficial to the workman and this in a way that the employer could appreciate because it touched his pocketbook—it was found to reduce the rate of industrial accidents.

Ordinarily accidents may be expected to vary directly with speed of production, owing to increased exposure to risk, but when fatigue is taken into consideration there is a marked modification of this rule. When there is a reduction of output due to fatigue there is a rise in the number of accidents; that is, in the last hours of the ten or twelve hour day, in spite of employees slowing up in work, more accidents occur. If for any reason production is speeded up in the last hours, when the laborers are fatigued, the number of accidents rises so rapidly as to leave no room to doubt that the higher accident risk accompanies the decline in working capacity of the employee. In general, the plant exhibiting the indications of heavier fatigue in output is also the plant subject to the higher accident risk.

Where does all this investigating lead? A few forward looking employers have been able to see for themselves that sodden drudges are not as desirable as workers who have leisure for recreation, for study, for health; organized labor is bringing the recalcitrant into line. But the duty of the scientist is clear. "To humanize working conditions, to reassert the value of the individual, to study all ways of releasing in work the best energies of the worker, instead of as now so prodigally wasting them, this should be the practical rôle of science in industry. And it is as a contribution to this new era of intensive study devoted to large ends that this report has been aimed."

TREATMENT OF TETANUS.

Castaigne and Paillard have recently given some complete and up to date data concerning tetanus when the disease has declared itself, and their remarks on the treatment are well worth considering. They point out that there are a certain number of conditions present which should guide the treatment when the disease has been confirmed. For instance, the subject has a wound which requires surgical care; he suffers from painful permanent contraction, to which intermittent paroxysms are added; a specific intoxication exists, as well as inanition and dehydration.

The first step in the treatment is the adminis-

tration of sedatives, keeping the patient absolutely quiet, preferably in a darkened room, and the avoidance of all unnecessary examinations. Hot baths (101° to 104° F.), lasting from half an hour to forty minutes and repeated every three or four hours, will lessen the contracture and result ultimately in a very pleasant sedation and occasionally sleep, which should be carefully guarded. The patient should be moved from place to place with the utmost care.

Of sedative medicines, chloral is recommended administered in doses varying from six to ten, or even fifteen grams, either in combination or not with four to eight grams of potassium iodide, by mouth or rectum. Chemically pure neutral sodium persulphate, preserved in closed ampoules, should be given intravenously in doses of five grams in one hundred cubic centimetres of sterile distilled water. Intraspinal injections of magnesium sulphate in a twenty-five per cent. solution—one cubic centimetre for every twenty kilograms of body weight—may be given once a day, or it may be given subcutaneously, in which case ten cubic centimetres of the twenty-five per cent. solution are given four times daily.

Morphine and chloroform are not so highly recommended, but the latter, when inhaled in small quantities, will relieve the pain of hyperacute tetanus.

The second aim of treatment is specific medication and its basis is serotherapy. Regardless of the lack of irrefutable proof, Castaigne and Paillard believe that clinical experience is decidedly in favor of this form of treatment. In the acute and subacute forms of tetanus a daily injection of twenty to thirty cubic centimetres of serum should be given during the first week, after which one every two or three days will suffice. The injection may be given subcutaneously or in the epidural space, but the latter route does not seem to offer any advantages over the former. Baccelli's method, which consists of forty centigrams to one gram of carbolic acid dissolved in oil or glycerin, according to the gravity of the infection and the patient's weight, is still a moot subject, but it can be resorted to in combination with other therapeutic measures. The injections should be given daily during the first week and afterward every second or third day.

Feeding is a most important factor in the treatment of tetanus, on account of the inanition and dehydration of these patients. Feeding by mouth is often impossible, or at best difficult, on account of the trismus and dysphagia, so that rectal feeding must be resorted to. Rehydration is obtained by the same route. Two rectal feedings and two

glucose serum rectal injections are to be given in twenty-four hours. One cleansing enema will be required daily. Glucose serum or salt solution can also be administered subcutaneously. The latter will be the ultimate resource when dysphagia exists and rectal intolerance is present. Lastly, accessory medicaments, such as camphorated oil as a tonic—one to three grams of camphor in twenty-four hours, subcutaneously, sparteine for the heart, and subcutaneous injections of oxygen, when contracture of the inspiratory muscles exists, must never be overlooked.

EDITORIAL ANNOUNCEMENT.

Beginning with this issue we shall publish a series of editorials about medical men in literature. Strange as it may seem, some of the greatest men in the literary world were physicians. Many of them were Americans. Rabelais will be the first physician author described, others will follow. A great deal of research was necessary to complete this work, which has been done by Jefferson Williamson especially for the *NEW YORK MEDICAL JOURNAL*.

These editorials will be intensely interesting. It will be well worth your while to read the entire series.

News Items.

Tampico Quarantined.—Quarantine against bubonic plague has been established in Tampico, Mexico.

Addition to Rockaway Hospital.—Plans are under way to erect a Soldiers' and Sailors' Building as an adjunct to the Rockaway Beach Hospital, in memory of Rockaway boys who served during the war.

Dr. William O. Pitt to Red Cross League.—Dr. William O. Pitt has been appointed chief of the Department of Child Welfare of the League of Red Cross Societies. He has been active in child welfare work in England since 1910.

War Invalids in Government Hospitals.—The Bureau of War Risk Insurance is embarking on a plan to concentrate convalescent veterans in hospitals owned and controlled by the Government. There are 17,981 disabled exservice men and women being cared for in more than 1,000 hospitals scattered throughout the United States, of this number 8,123 are in Government hospitals and 9,858 in private or state and county hospitals and sanatoria.

Radium Soon Available.—On and after October 15th, the New York State Institute for the Study of Malignant Diseases, in Buffalo, will administer the two and one quarter grams of radium which the state legislature recently enabled it to purchase by an appropriation of \$225,000. Any citizen of the United States will be treated free of charge at Buffalo, but preference will be given to residents of New York State. Dr. Harvey R. Gaylord is director of the Institute.

Award to Dr. Pende.—The Balbi-Valier prize offered by the Venice Reale Istituto has been awarded to Dr. Nicola Pende, professor of pathology in the University of Palermo, for his works on the organs of internal secretions.

Honorary Degrees.—Cambridge University has conferred the honorary degree of Doctor of Laws upon Dr. John Jacob Abel, professor of pharmacology at Johns Hopkins Medical School, and Dr. Harvey Cushing, professor of surgery at Harvard Medical School.

Maryland Health Department Enlarged.—A department of bacteriology has been established by the Maryland State Board of Health, under the direction of Dr. R. C. Salter, and a new venereal disease department under the direction of Dr. Walter Brunet.

Woman Physician Decorated.—Dr. Blanche Norton, of Eldon, Iowa, has been awarded the Order of King George I by King Alexander of Greece. Dr. Norton, a physician of the American Committee for Relief in the Near East, distinguished herself at Kerrassunde, Anatolia, by treating Greek orphans with trachoma. She contracted the disease herself but has since recovered.

Florida State Medical Association.—The Florida State Medical Association met May 12th and 13th at Daytona and elected the following officers: President, Dr. William E. Ross, of Jacksonville; vice-presidents, Dr. Clyde C. Bohannon, of Daytona; Dr. George A. Davis, of DeLand; Dr. James H. Fellows, of Pensacola; secretary-treasurer, Dr. Graham E. Henson, of Jacksonville. Pensacola was selected as the next place of meeting.

Municipal Milk.—The city council of Manchester, England, has voted to municipalize the distribution of milk.

The health committee's arguments in support of the proposal were that as supplied at present Manchester milk would all be classed C3 according to American grading, and would be allowed for use only for cooking and for manufacturing purposes; that impure milk was largely responsible for tuberculosis in children, and that one third of the deaths of children under five years of age could be attributed to bovine infection. Adulteration was so common that Manchester citizens paid £35,000 yearly for water.

Tuberculosis Research Fellowship.—To encourage study of the means for the prevention and cure of tuberculosis, the Hennepin County Tuberculosis Association of Minneapolis, has set aside a fund for the support of a tuberculosis research fellowship in the graduate school of the University of Minnesota. The candidate for the fellowship must be a graduate of a Class A medical college. He will be expected to devote himself to research in some problem concerned with the causes, prevention or cure of tuberculosis. No teaching or other service will be required. The fellowship yields \$750 the first year and progressively increasing amounts to be appropriated for the second and third years as conditions warrant.

Inquiries and requests for application blanks should be addressed to the dean of the graduate college, University of Minnesota, Minneapolis.

Dr. Villard Elected to Faculty of Lyon.—Dr. Villard, surgeon to the Hotel-Dieu and an editor of the *Lyon medical*, has been named professor of operative medicine at the University of Lyon, to succeed Prof. Maurice Pollosson, resigned.

International Health Journal.—The *International Journal of Public Health*, which makes its first appearance with the July number, is the official scientific organ of the League of Red Cross Societies. Dr. Thomas R. Brown is the editor, Dr. W. W. Francis is the associate editor, and the assistant editors are Miss Harriet Bailey, Mr. Marshall Balfour, Dr. Garcia Banus, Mr. Walter Clarke, Dr. E. F. Ducasse, and Dr. Lina M. Potter. The *Journal* will be published every two months and will appear in four editions, English, French, Italian and Spanish. It will be devoted to all phases of public health and preventive medicine.

New Medical Journal in Palestine.—Palestine's first medical journal, a quarterly entitled *Harcfoosh* (Medicine), has just made its appearance, published by the Jewish Medical Association of Palestine. Medical work in Palestine has been greatly stimulated during the past two years by the physicians and nurses with the American Zionist Medical Unit, who have taught the native members of the profession modern methods. The hospitals and clinics established by the American unit in Palestine are planned as the beginning of the Medical College of the Hebrew University at Jerusalem.

Hookworm and Tuberculosis.—Information with regard to mistaken diagnosis in the case of tuberculosis and hookworm is contained in a preliminary report received by the War Department on a study conducted by army medical men at General Hospital No. 19, at Oteen, N. C., where tuberculous patients are treated. The report says that many cases which had been diagnosed as tuberculosis on further examination showed signs of hookworm, and under treatment for hookworm the patient improved greatly. Accurate figures as to the number of hookworm cases which had shown all the evidences of tuberculosis will soon be compiled. It is estimated that about ten per cent. of the patients suffer from hookworm at the time of admission and that about two per cent. do not have tuberculosis.

Died.

BAKER.—In Dennison, Ohio, on Sunday, August 1st, Dr. Charles Wesley Baker, of Kilgore, aged forty-seven years.

CONCANNON.—In New York, N. Y., on Sunday, August 1st, Dr. James J. Concannon, aged sixty-four years.

CROWLEY.—In Potsdam, N. Y., on Sunday, July 25th, Dr. William H. Crowley, of Chicago, aged fifty-three years.

HARDING.—In Topeka, Kan., on Tuesday, July 27th, Dr. Eva Harding, aged sixty-three years.

HUGHES.—In Boston, Mass., on Friday, July 30th, Dr. Laura Ann Cleophas Hughes, aged sixty years.

JONES.—In St. Louis, Mo., on Tuesday, July 27th, Major D. C. Jones, of Leavenworth, Kan., aged eighty-two years.

KENNY.—In New York, N. Y., on Saturday, July 24th, Dr. John Joseph Kenny, aged thirty-seven years.

PARKER.—In Southampton, Pa., on Saturday, July 24th, Dr. George Albertson Parker, aged sixty-six years.

QUINT.—In Boston, Mass., on Monday, July 26th, Dr. Norman Perkins Quint, of West Medway.

Book Reviews

FRIEDRICH HEBBEL

Friedrich Hebbel. Ein psychoanalytischer Versuch. By Dr. J. SADGER, *Schriften zur angewandten Seelenkunde.* Edited by Prof. Dr. SIGMUND FREUD. No. 18. Vienna: Franz Deuticke, 1920. Pp. 374.

"My purpose is to write an entirely sincere book—the reader will judge if I have succeeded—that is, to draw the man Friedrich Hebbel as he appears to me, not merely in his merits and his great accomplishments but also with all his many weaknesses. This will be seen not to be due to a lack of appreciation of the genius which has given the world such great, such immortal gifts. It seems to me that genius is little served when one pours out only psalms of praise, for it is only to the gods that incense is not a poison; it befogs and stupefies earth-bound man, veiling the truth. And to find the truth, with favor to no one, but also with injury to no one, seems to me the first task of the investigator."

This latest volume in the psychoanalytical series of the *Schriften zur angewandten Seelenkunde* is thus introduced by the author. This author has written earlier (*Von der Pathographic zur Psychographic. Imago* Vol. 1, No. 2, p. 158) explaining the difference between such scientifically psychological search for truth through understanding of a human life and its work and that of the blind and pointless method of applying a certain amount of superficial psychological skill to the study of a writer and exercising perhaps a prurient delight in destroying the world's idols. The sincere purpose of the author and the thoroughly openminded and faithful manner in which he has carried it to fulfillment show how far genuine psychoanalytical study stands above a superficial dabbling with human lives or human achievements. If one reads again thoughtfully the words quoted above from the author's preface, one will find full justification for presenting this study even to a group of readers outside Hebbel's own country and where his works are comparatively little known. This justification is made more complete by an examination of the contents of the book.

In the first place, the author's point of view shows us the value that such a study of any life may have. For the reader finds here what is promised, a study of the characteristics of a man, the strong and the weak, and of his performances in the light of his entire life, with particular emphasis upon his childhood. In this way the contradictions of his personal life, the power of his creative work, as well as its limitations, become comprehensible. To submit any life, its character and its products, to such careful and penetrating scrutiny yields rich results for enlarging psychoanalytical knowledge. Such is the case with this book. So keen and faithful is the search for underlying psychic facts and the portrayal of these as discovered, the discussion of the elements of environment which play upon a life and, more important still, the reactions of such a life to these environmental factors, that the reader is compelled also to a persistent probing and analysis of self throughout the reading.

The subject of this book affords, moreover, specially rich material for such investigation, material which is peculiarly fitted to bring home these searching and therefore wholesome truths. Hebbel is a poet who attracts psychoanalytical study. In the first place, he himself has given much information concerning his own inner life and the feelings and experiences of his childhood in his reminiscences and his diaries. Moreover, in doing so he has revealed, just as he has in all his creative writing, an acknowledged belief in the unconscious with its storehouse of creative impulses and its reserve material of phantasies. Along with this he reveals a striking appreciation of the dream, of its close relation to artistic creation, and of its function in the life of the dreamer. Besides, the creative works of the poet reveal the close relation of these to his own unconscious content, the limitations and imperfections of this poetry revealing the infantile complexes which to a large extent always dominated him.

These are plainly traceable, largely through the testimony he himself has given, to the infantile period of his life and to the sexual difficulties which there built themselves around both parents and around other objects of his environment. These were not necessarily directly sexual in the adult sense of the word but richly illustrative of the infantile sexuality which it has been discovered played such an enormously important part in determining his later life and production. The writings of the poet testify to the power bound with these complexes which in part found sublimation into works of force and strength, serving thus to discharge in really great form these infantile libido trends and thus furnish release for the poet and for his audiences. At the same time they, too, largely filled his plots and their developments and therefore, because of their often too insistent and too grossly exaggerated infantile character, they failed to establish the hold upon the world that they otherwise might have had. In his personal life they played a still more disturbing part. The man Hebbel was governed too strongly, too compulsively, by these factors to fulfill his part as lover, husband, father, friend, in the best way. His inability to free himself from the infantile bondage to either parent seriously marred his relations with his fellow beings and brought suffering to many in his train.

The details of his character and of its development from its early determinants are largely those of the compulsive neurotic. The elements of his partial success, great and imposing as far as it was attained, as well as his weaknesses and failures, serve to throw much light upon the makeup of such a neurosis, the difficulties with which such a character must contend, its manner of meeting these difficulties in overcoming or succumbing to them, and upon the infantile experience out of which such a form of character arises. Therefore the study of a man who reveals in such large measure the elements of both greatness and weakness, bound together in such a condition, is an invaluable human document. Added to these revelations of human character, of

the striving of human elements which speak through his writings, is his definite teaching regarding psychic material and the mechanisms, such as the dream, through which it reveals itself. English readers must acknowledge, therefore, beyond the general psychoanalytical debt to Sadger, their indebtedness to him for the opportunity to become better acquainted with this poet of the unconscious of another land and tongue.

OPHTHALMOLOGY.

A Practical Treatise on Ophthalmology. By L. WEBSTER Fox, M. D., LL. D., Professor of Ophthalmology, Medico-Chirurgical College Graduate School; University of Pennsylvania, etc. Illustrated. New York: D. Appleton & Co., 1920. Pp. i-831.

This new edition of Fox's follows the older edition fairly well. The new technic which the author devised for the relief of conical ulcer has been added to the original test. The author's experience with this operation causes him to recommend it highly. His description is given in detail and can be followed with ease. He also describes an operation of great simplicity which he uses for the excision of the tarsal cartilage in trachoma. He has described the Elliot operation for glaucoma with the Fox modifications for comparison. Some space has been given to the use of biological tests in diagnosis and treatment. This is important and carefully worked out and should prove of great interest. Much work has been done in this field experimentally and it is encouraging to find it incorporated in a textbook with the merits of this one.

HUMAN COSTS OF WAR.

The Human Costs of the War. By HOMER FOLKS. Organizer and Director of the Department of Civil Affairs of the American Red Cross in France and Later Special Commissioner to Southeastern Europe. Illustrated with photographs by Lewis W. Hine. American Red Cross Special Survey Mission. New York and London: Harper & Brothers. Pp. i-326.

Homer Folks is qualified to write about the *Human Costs of the War*. After all there are only two things to consider: The human costs and the effect of the war on human progress. If those who say they are so weary of war stories would spend the same amount of energy in decrying war, wars would be at an end. But it seems consistent with human folly to refuse to face the products of our own making, so that we may be able to repeat our crimes with a clear conscience.

This survey is a rather extensive one and covers most of Europe. The horrors of the country that suffered most, Serbia, are told clearly and dispassionately. These rather primitive people were able to stand their hardships better than any other Europeans. We are shown how typhus ravaged the country and overflowed from the hospitals into the cemeteries. Typhus, while the most deadly enemy of the Serbians was not the only one. Tuberculosis, syphilis, typhoid, dysentery and malaria were encountered on every hand. Other barbarities of human making are also described and some of the recorded deeds of Serbia's neighbors are none too esthetic—some of the acts of the Serbians, however, are not given. When the cultural level of these Balkan people is considered their acts should cause

less wonderment than those of some of the more civilized countries. None of the little games of revenge played by people at war can bear close scrutiny.

We are also shown the gruesome pictures of Belgium, France and Italy and finally wavering Greece holding out for more gain. Then comes the summing up with the question: What is our civilization, what has it done? It has caused epidemic and death by violence, misery, and unhappiness—all through the maneuvering of a few senile statesmen. There were nine million soldier dead, ten million homeless, fifty million manless homes, ten million empty cradles, disease, death, desolation. How can one face these figures and favor war? How much can we who remain do to retrieve the results of this madness and folly? Perhaps we here in America have grown so accustomed to large figures that these will mean little; perhaps a few months in a vermin infested dugout decorated by decaying bits of our former comrades would be a more effective lesson; perhaps—but it is so difficult to measure sorrow and count the broken souls who suffered and were left behind. Is it fair to forget this bloody lesson in the joys and comforts that surround us?

THE PRIMITIVE IN POETRY.

The Golden Whales of California. And other rhymes in the American language. By VACHEL LINDSAY. New York: The Macmillan Company, 1920. Pp. iii-181.

Poems by a Little Girl. By HILDA CONKLING. With a Preface by AMY LOWELL. A Portrait by James Chapin. New York: Frederick A. Stokes Company. Pp. v-120.

These two books of poetry are, at first glance, as far apart as they can be, yet when more closely examined they present an analogy that may be well worth recording—Vachel Lindsay, a poet of standing, well known to followers of American verse, and Hilda Conkling, a little girl of nine, the one writing about all manner of things, most of them familiar to all of us, and the child telling her impressions to her mother.

Now where, you may ask, do we find common ground? On the one hand we find the crude primitive cadences used to describe the passing puppet shows, while the child gives voice to her musings little touched by the adult knowingness which comes from contact with the world. The one makes use of the infantile expressions of the race, while the other uses the lyrical images of her infantile life. Both use the lower, more primitive levels for their medium of expression.

Vachel Lindsay has popularized the booming melodies of negro chants; he has used them to describe prize fights, political conventions, and camp meetings. He has felt the throbbing pulse of the unsuppressed rhythmic heart beats of those unshackled by culture; he has woven these into strong stanzas which carry one away in a wild ecstasy. The child, unrestricted by the continual don'ts of nursemaids, as Amy Lowell so carefully explains, has presented her phantasies to her understanding mother. She, too, has clung rather tenaciously to reality and her phantasy has served to harmonize and make beautiful the little things about her and not as a retreat wherein she can escape from the world of reality. In both instances free-

dom, unrestraint and wholesomeness, are expressed.

The argument may be raised that all rhythmic expression is more or less primitive and has an underlying sex motive which it seeks to express. But there is a vast difference in the way it is used. We find the Chinese with their delicate fragments dating back to antiquity, Keats with his sophistication, Browning in his mystic intricacies, Maeterlinck in his symbolic musings, Longfellow's sentimentality, the self pity of Oscar Wilde, and the ponderousness of Wordsworth. Few are content with the purely primitive.

In Russia poetry and other means of expression in children have received more attention than in many other countries. The drawings, verses, and writings of children have been collected there for many years and much original material revealed. They have shown that frequently the phantasy minds of the children, prior to the time that their minds are pressed in the great conventional mold, give rise to many creations of rare beauty. Perhaps we, too, would find much of interest and not a little instruction if we were to give more encouragement to the thoughts and productions of children, if we would try to teach them less of the dry material we have to offer them, and learn more from them when they sing to us the melodies of their child souls or try to paint life as they see it before they are crushed in the mold of our making.

MYSTERY AND THE NEUROTIC.

The Vanishing Men. By RICHARD WASHBURN CHILD, Author of *Velvet Black*, etc. New York: E. P. Dutton & Co. Pp. i-324.

Most mystery stories are rather flimsy affairs. They are written with the object of putting down enough words on paper, using a rather circular plot and then trusting that the run of the book will be up to the average and so prove a successful business venture. This does not apply in the case of *Vanishing Men*. Carefully written, so as to hold attention to the last page; many thrills, and all the trimmings demanded of a worthy mystery tale and yet there is something more. The author has taken advantage of the little bypaths. The descriptive bits are very real and very beautiful. Most worthy of all, however, is his description of fear. One of the chief characters in the book is a man with a remnant of worth trying to disclose itself through a mass of less worthy characteristics. With great precision we find portrayed a hypochondriacal person who in the shifting of life's scenes makes a monetary success, but is a bankrupt in soul. Gradually the hypochondria becomes replaced by an anxiety neurosis and here Child draws a convincing clinical picture. He makes use of the dramatic material presented and handles it exceedingly well. Another point of interest is the projection of the fears to a harmless individual, the heroine. This is so subtly done that in time she herself feels that through some supernatural power she brings destruction to those who know her. But in the solving of the human riddle we find here as always these mystic forces are nothing but the interpretation of man's fears and weaknesses. There are many of these in the book and not until it is finished do we see them clearly.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

MAN'S UNCONSCIOUS CONFLICT. A Popular Exposition of Psychoanalysis. By WILFRED LAY, Ph.D. New York: Dodd, Mead & Co, 1919.

THE CHILD'S UNCONSCIOUS MIND. The Relations of Psychoanalysis to Education. By WILFRED LAY, Ph.D. New York: Dodd, Mead & Co., 1920.

HELLENIC ARCHITECTURE. Its Genesis and Growth. By EDWARD BELL, M.A., F.S.A. Illustrated. London: G. Bell & Sons, Ltd., 1920. Pp. xx-185.

KNOWLEDGE ENHANCED. Phenomenon of Sleep Solved. By LUTHER STOCKTON FISH. Illustrated. Cleveland, Ohio: Published by the Author, 1920. Pp. viii-297.

MORTALITY STATISTICS, 1918. Department of Commerce, Bureau of the Census. SAM L. ROGERS, Director. Nineteenth Annual Report. Washington: Government Printing Office, 1920. Pp. iii-603.

A GENERAL INTRODUCTION TO PSYCHOANALYSIS. By Prof. SIGMUND FREUD, LL.D. Authorized Translation, with a Preface by G. STANLEY HALL, President, Clark University. New York: Boni & Liveright. Pp. i-402.

MINISTRY OF THE INTERIOR, EGYPT—DEPARTMENT OF PUBLIC HEALTH. Sixth Annual Report on the Ophthalmic Section, 1918. By the Director of Ophthalmic Hospitals. Cairo, Egypt: Government Press, 1919. Pp. viii-30.

THE USE OF COLLOIDS IN HEALTH AND DISEASE. By ALFRED B. SEARLE. With Foreword by Sir MALCOLM MORRIS, E.C.V.O. Illustrated. London: Constable & Co., Ltd., 1920; New York: E. P. Dutton & Co. Pp. vii-120.

DAWN OF THE AWAKENED MIND. By JOHN S. KIND, M.D., Founder and President of the Canadian Society for Psychical Research for the eight years of its existence. Illustrated. New York: James A. McCann Company, 1920. Pp. xxix-451.

THE FACULTY OF THE COLLEGE OF PHYSICIANS AND SURGEONS. Columbia University in the City of New York. Twenty-four Portraits by DORIS U. JAEGER. With a Foreword by SAMUEL W. LAMBERT, M.D., A.B., A.M., Ph.B. New York: Paul B Hoeber, 1919.

THE PRINCIPLES OF ANTENATAL AND POSTNATAL CHILD PHYSIOLOGY, PURE AND APPLIED. By W. M. FELDMAN, M.B., B.S. (Lond.), Assistant Physician to and Lecturer on Child Physiology at the Infants' Hospital. Illustrated. London and New York: Longmans, Green & Co., 1920. Pp. xxvii-694.

ALBANY: THE CRISIS IN GOVERNMENT. The History of the Suspension, Trial and Expulsion from the New York State Legislature in 1920 of the Five Socialist Assemblymen by Their Political Opponents. By LOUIS WALDMAN. With an Introduction by Seymour Stedman. Illustrated. New York: Boni & Liveright. Pp. xx-233.

DISEASES OF THE INTESTINES AND LOWER ALIMENTARY TRACT. By ANTHONY BASSLER, M.D., Professor of Gastroenterology, Fordham University Medical College and New York Polyclinic Medical School and Hospital; Visiting Physician, New York Polyclinic Hospital, etc. Illustrated. Philadelphia: F. A. Davis Co., 1920. Pp. xvi-660.

ADVANCED LESSONS IN PRACTICAL PHYSIOLOGY FOR STUDENTS OF MEDICINE. By RUSSELL BURTON-OPITZ, S.M., M.D., Ph.D., Associate Professor of Physiology, Columbia University; Professional Lecturer in Physiology in Teachers' College and the Extension Department of Columbia University. Illustrated. Philadelphia and London: W. B. Saunders Co., 1920. Pp. xiii-238.

HUMAN PARASITOLOGY. With Notes on Bacteriology, Mycology, Laboratory Diagnosis, Hematology and Serology. By DAMASO RIVAS, B. S. Biol., M. S., M. D., Ph. D., Assistant Professor of Parasitology; Assistant Director of the Course in Tropical Medicine and of the Laboratory of Comparative Pathology and Tropical Medicine in the University of Pennsylvania, etc. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920. Pp. vii-715.

Miscellany from Home and Foreign Journals

Epidemic Encephalitis.—L. P. Stephen and K. M. Bulchandani (*Indian Medical Gazette*, March, 1920) thus describe this disease as observed in Karachi. The onset may be acute and fulminant, or be insidious and take a more or less benign course. Very young children are rarely attacked; most patients are from fifteen to forty years of age. Five out of six are males. Cases are found in all grades of society. The onset is mostly insidious, with generally a stage of excitement at first. The patient may show nothing but a marked eccentricity and an easy excitability on slight provocation, and may have hallucinations and delusions. In other cases a sudden diplopia is the first symptom. Sooner or later the subject becomes lethargic and looks very sleepy. He lies with drooping eyelids, unconcerned about himself and his surroundings, has little or no initiative, and at the height of the disease may show a complete lack of spontaneous motion. If questioned a short intelligent response can generally be elicited, after a delay. Various types of paralysis appear, always related to cranial nerves and apparently of nuclear origin. Sensory nerves are rarely involved. Among other symptoms are general rigidity of the limbs, not always present, slight retraction of the head, tremors of the muscles of the face and limbs, sometimes restless movements of the latter. Muscular power is weak. Sugar may appear in the urine. Reflexes are present as a rule. There is little or no tendency to bed sores. In fulminant cases the patient may be struck down suddenly, become unconscious, and die sooner or later. Constipation is another definite feature. The tongue has a thin whitish coating and is large, thick and slightly indented at the edges. The breath is foul, the appetite unimpaired, the liver and spleen not enlarged. Retention of urine may be one of the first symptoms, or may appear later, to be still later replaced by involuntary passage of urine. Fever is generally present, the temperature ranging from 100° to 101° F., but rising to 104° or 105° in unfavorable cases. The skin is usually moist and there may be profuse perspiration. A rash, either rose or purpuric, may appear early or not until the thirteenth day.

In favorable cases the temperature falls by lysis, the patient begins to take interest, and his symptoms improve. Ptosis is generally the last symptom to disappear. In unfavorable cases with high temperature and acute toxemia the patients die of asthenia or edema of the lungs. The pathological changes described are those of hemorrhagic encephalitis. There may be pin point aggregate foci of hemorrhage more frequently in the mesoencephalon than elsewhere. A sort of patchy diffuse meningitis with cellular exudate has also been found. All cases showed a moderate amount of leucocytosis and were negative to blood parasites. The cerebrospinal fluid was clear and under no pressure. Concerning the nature of the disease, the writers do

not believe it to be connected with influenza, but refuse to venture an opinion as to whether it is a new disease or not. As regards treatment, calomel in fractional doses and salines are useful to relieve constipation and lessen intestinal auto-intoxication. Eserine was found to be of little use. Urotropin in gram doses was given without noteworthy results, but its use is recommended as the only useful antiseptic in cerebrospinal infections. Three patients were treated with an intravenous injection of salvarsan, after which the improvement was very rapid and striking.

The Virus of Lethargic Encephalitis.—C. Levaditi and P. Harvier (*Presse médicale*, March 31, 1920) have succeeded in reproducing encephalitis in a rabbit by intracerebral inoculation of an emulsion of gray matter from a human case of the disease. Upon repeated passage through rabbits the virus became a fixed virus and exhibited the property of killing the animal in from four to six days. The animal showed a torpid state, myoclonic manifestations, and symptoms of meningeal irritation. Postmortem there were found typical encephalitic lesions analogous to those described in man. The virus, which is not cultivable by the ordinary methods, may be kept in glycerine. It is a filterable virus, easily passing through No. 1 and No. 3 Chamberland filters. It can be inoculated into the rabbit not only by the cerebral route but also by way of the peripheral nerves. After repeated passage through rabbits it becomes pathogenic for the lower catarrhine ape. The general conclusion reached is that the virus is a specific, filterable virus, plainly distinct from that of epidemic poliomyelitis.

Lethargic Encephalitis.—Combemale and Duhot (*Bulletin de l'Académie de médecine*, April 13, 1920), among twelve cases of lethargic encephalitis seen at Lille, found a considerable variation in the earlier symptoms, some cases exhibiting a sudden onset with vomiting and distinct constitutional reaction and others beginning insidiously with somnolence, at first intermittent and later continuous. In some cases visual disturbances constituted the initial symptom, leading the patient to consult an oculist. Hypersomnia ranged from simple apathy to profound lethargy. Delirium and restlessness sometimes developed at night. At times there was distinct catatonia, and two patients presented, especially during convalescence, certain features suggesting Parkinson's disease. Most cases showed at least temporary diplopia. One third of the cases had internal ophthalmoplegia, and the possibility of facial or velopalatine paralysis was also noted. The knee jerks were generally exaggerated, sometimes unequally on the two sides; in two cases they were absent. Fever was variable, constipation frequent and obstinate, and marked loss of weight generally observed. Low blood pressure was found to be an important feature. The cerebrospinal fluid generally issued at high pressure; albumin was

normal or slightly raised, and sugar rather increased than diminished. Lymphocytosis in the cerebrospinal fluid was constant but slight; sometimes it persisted even after disappearance of the clinical signs. Urea in the blood and cerebrospinal fluid was high in the grave cases. In the diagnosis, the cerebrospinal fluid should always be taken into account. Marked lymphocytosis and hyperalbuminosis suggest rather a meningeal reaction due to tuberculous or syphilitic infection or to mumps, while slight lymphocytosis and slight or absent hyperalbuminosis confirm the suspicion of lethargic encephalitis, excluding from the start a neurosis or ordinary infection. The prognosis may be based upon the same series of factors. Death seems to occur in two ways. In some instances there are evidences of infection and fever, which may be very high; the rise in the temperature, either progressive or following a remission, is the most important sign. In the other group death takes place through secondary intoxication, gradual increase of the blood urea occurring as an indication of oncoming tissue disintegration.

Intraspinal Injection of Antitetanic Serum in Lethargic Encephalitis.—Laubie (*Bulletin de l'Académie de médecine*, March 16, 1920), having treated some cases of lethargic encephalitis with urotropin and collargol, without benefit, administered, in two subsequent cases, intraspinal injections of antitetanic serum, previously used with success by De Coquet in a case of encephalitis with pronounced rigidity, suggesting tetanus. In Laubie's first case thus treated, the injection, given on the fourth day, was followed in thirty-six hours by marked improvement, the temperature descending and the dyspnea, ptosis, photophobia, neck rigidity and somnolence passing off. In this case lumbar puncture had yielded clear fluid showing a little albumin, a few lymphocytes, no bacteria, and negative Noguchi and Bordet-Wassermann tests. The second patient exhibited somnolence, slow speech and movements, rigidity of the neck, and positive Kernig's sign. Lumbar puncture yielded fluid containing a few erythrocytes, 0.78 of albumin, no bacteria, and a weakly positive Noguchi. Injection of tetanus antitoxin was followed by disappearance of rigidity and Kernig's sign in forty-eight hours, and subsequently, of the other manifestations of the disease.

Lethargic Encephalitis.—G. Marinesco (*Bulletin de l'Académie de médecine*, March 16, 1920) notes that the more recent epidemic of this affection appears to include a considerable number of mild and atypical cases, in particular the ambulatory, myoclonic and meningeal forms, which were not seen in previous epidemics. He reports a case in a woman aged twenty-two, with pronounced lethargic and cataleptic symptoms but with preservation of the functions of the sensorium. The spinal fluid at first showed a marked lymphocytosis, and the temperature eventually rose above 41° C. The patient died twenty days after the onset. Post-mortem examination showed as the chief pathological disturbance an inflammation of the small and precapillary veins, the lymphatic sheaths of which were infiltrated with numerous lymphocytes, mon-

onuclears, plasma cells, and fibroblasts. Where destruction of medullated fibres or hemorrhagic foci occurred, macrophages laden with fat or pigment were seen. New formation of capillary vessels was likewise detected. Disseminated foci of hemorrhage were found in the gray substance of the floor of the fourth ventricle and of the aqueduct of Sylvius. No corresponding inflammation of the arteries could be found. The infundibulum was but slightly involved and the hypophysis not at all. The pathological changes were not limited to the corpora quadrigemina and cerebral peduncles, but had extended to the thalamus and metathalamus, the telencephalon, the corpus striatum, and even the cerebral cortex. In the medulla, pons and peduncle there was marked infiltration of the vessels of the raphe. The raphe and even the nerve roots of the hypoglossal, glossopharyngeal, and pneumogastric showed foci containing not only mononuclear lymphocytes and plasma cells but also, and chiefly, enlarged and proliferated neuroglia cells of the fibrous type. Inflammation of the neuroglia about the blood vessels was manifest in all the cases of lethargic encephalitis examined post-mortem by the author. Attention is called to the similarity of the pathological changes in lethargic encephalitis to those found in African sleeping sickness, general paralysis, and infantile paralysis. On the whole, no pathological peculiarity completely distinctive of lethargic encephalitis is as yet known. Neuroglia nodules have been found in the dentate nuclei, white matter, and other portions of the cerebellum by the author as well as by Charles Box. The pathogenic agent is asserted to be different from those of influenza and of infantile paralysis. It is probably propagated by the throat secretions. It is carried by the lymphatic vessels to the mid-brain and medulla, where the most pronounced pathological changes are found.

Serpiginous Character of Lethargic Encephalitis.—C. Achard (*Bulletin de l'Académie de médecine*, April 6, 1920) points out that the protean character of the clinical picture in lethargic encephalitis applies not only to different cases but likewise to the individual case, in which widely divergent clinical manifestations may follow one another in close succession. One patient had had the characteristic somnolence for one week before admission to a hospital. Upon admission he talked volubly, showed interest in his surroundings, moved without difficulty, and sat up in bed, but complained of left frontal headache. Next day the temperature rose to 39.2° C. and lumbar puncture yielded a hemorrhagic fluid which remained yellow upon centrifugation. Three days later fluid presenting these same features was withdrawn. The temperature remained above 38° C. for a week. Suddenly, after defervescence and marked diminution of the headache, complete paralysis of the left oculomotor nerve appeared. Had the initial disturbance not been known, independent diagnoses of meningeal hemorrhage and later of oculomotor paralysis, both of obscure origin, might have been made. The left pupil was dilated and unresponsive to light in this case. Reference is made to a similar case, with initial som-

nolence, reported by Achard and Paiseau in 1904, which was probably one of lethargic encephalitis. Stress is laid on successive stages marked by different clinical phenomena as a diagnostic feature in this disease. This variation of the symptoms may be correlated with present knowledge of the pathology of the disorder. The brain lesions, chiefly vascular in their localization, may affect different nervous structures to a varying extent and for variable periods of time, passing from one point of the midbrain to another, and also to the cerebral hemispheres and spinal cord. The course followed by the lesions is serpiginous, and this is perhaps the most singular feature of the disease, for no other form of encephalitis, whether acute or chronic, presents it to such a high degree.

Clinical Signs and Meningeal Reaction in Lethargic Encephalitis.—Jeanselme (*Bulletin de l'Académie de médecine*, April 6, 1920) reports a case of lethargic encephalitis in which the initial soporose and paretic stage of the disease was followed by a stage of myoclonic movements and a third stage of choreiform manifestations and atetosis. He discusses the question whether these later manifestations should be looked upon as sequelæ or as the expression of a recrudescence of the encephalitis. Three lumbar punctures carried out at successive intervals of two weeks and one week proved highly significant in this connection. The first puncture showed thirteen lymphocytes and 1.5 grams of albumin; the second, three lymphocytes and 0.5 gram of albumin, and the third, twelve lymphocytes, 0.8 gram of albumin and 0.38 gram of sugar. Thus, during the soporose and paretic stage there was slight but distinct meningeal irritation. During the remission which preceded the manifestations of incoordination the meningeal reaction was perceptibly lessened. Finally, upon appearance of the myoclonia and chorea, a recrudescence of the meningeal reaction took place. In view of the close agreement between the clinical symptoms and these puncture findings, the myoclonia and chorea need not be considered as sequelæ appearing during convalescence but as a new stage in the active course of the disease, doubtless associated with migration of the pathogenic agent to different structures.

Increased Cerebrospinal Sugar Content in Epidemic Encephalitis.—C. Dopter (*Bulletin de l'Académie de médecine*, March 2, 1920) refers to the case of a man, aged twenty-five years, complaining of slight frontal headache and general lassitude, dull pain in the right scapular and cervical regions, diplopia, accommodative asthenopia, slight external strabismus, mydriasis, paresis of the lips on one side, doubtful Kernig sign, and slight fever. Ten months before, this patient had had a chancre and had been treated with novarsenobenzol; hence a tentative diagnosis of syphilitic meningitis was made, though the Bordet-Wassermann test was negative. The cerebrospinal fluid was clear and contained twelve lymphocytes per cubic millimetre and some albumin. Sugar, however, was found present in the unusual amount of 0.85 gram per litre. This finding was taken to exclude both syphi-

litic and tuberculous meningitis, and lethargic encephalitis was suspected. Next day the patient showed marked restlessness and delirium, followed by myoclonic twitchings and somnolence; death took place a week later. From previous personal cases and the present case, as well as from the observations of other clinicians, Dopter concludes that increase of sugar in the cerebrospinal fluid is of value in differentiating lethargic encephalitis from meningitis in its various forms. This increase doubtless results from hyperglycemia, due in turn to disturbance of the floor of the fourth ventricle. In tuberculous meningitis sugar in the cerebrospinal fluid is diminished or entirely absent, while in syphilitic meningitis it is generally normal in amount and only exceptionally in excess. It should be borne in mind that increased sugar content may occur also in affections other than epidemic encephalitis, e. g., diabetes, uremia, pneumonia, Malta fever, rabies, pertussis, brain tumor, amyotrophic lateral sclerosis, cerebral hemorrhage, and occasionally in chronic nervous syphilis. Furthermore, the sign is not constant in epidemic encephalitis. In one case examined late in the course of the disease, the sugar content was subnormal. Possibly in cases of encephalitis high up, without involvements of the bulbopontine region, excess of sugar is not to be expected.

Lethargic Encephalitis.—A. Pic (*Lyon médical*, March 25, 1920) reports a case of epidemic encephalitis unattended with somnolence, and thinks the term lethargic encephalitis might with advantage be replaced by acute epidemic superior poliomyelitis, at least in some cases. By way of prophylaxis, antiseptics of the mouth and pharynx of patients and convalescents, as well as among the contacts and ordinary influenza cases, is indicated, the pathogenic agent apparently entering through the nasopharynx and persisting there. In the treatment, lumbar puncture may be of service in a few cases with meningeal reaction, and hexamethylenamine is also useful. To stimulate the leucocytes, colloidal metals and the fixation abscess are available, as are also subcutaneous injections of oxygen for detoxicatory purposes. Warm baths or the hot pack, together with an icebag to the head, may be used for sleeplessness, nerve pains, restlessness, and meningitic symptoms. Adrenalin is useful for heart weakness and low blood pressure, as in ordinary influenza. For insufficient diuresis, rectal injections of isotonic glucose solution by the Murphy method may be employed. By such means the mortality—so far reported as twenty-five to thirty-five per cent.—may be lowered.

Experimental Research on the Virus of Lethargic Encephalitis.—C. Levaditi and P. Harvier (*Bulletin de l'Académie de médecine*, April 20, 1920) note that on February 10, 1920, they were successful for the first time in inoculating a rabbit with the disease, using an emulsion of brain tissue from a case of encephalitis in a woman aged forty-five. The tissue was obtained aseptically from the cortex, midbrain and medulla, and was inoculated in the dose of 0.2 mil into the brains of two rabbits and

one monkey. One of the rabbits died on the eighth day. Cultures of the brain and cardiac blood were sterile, and the nerve centres showed the typical lesions of meningoencephalitis of the cortex and midbrain. The two other animals showed no disturbance whatever. An emulsion of brain tissue from the dead rabbit was inoculated in the same dose into two other rabbits, which died on the sixth and seventh days, respectively, and showed identical brain lesions. The virus from one of these rabbits was subsequently passed through a number of other animals in succession. The experiments showed that the incubation period of the disease after intracerebral inoculation averages four or five days. Symptoms appear only a few hours before death and consist of a torpid condition with signs of meningeal irritation and epileptoid and myoclonic spasms in the limbs or choreic movements. The virus can be preserved in glycerin, and is a filterable virus, readily passing through the Chamberland filters Nos. 1 and 3. The virus may be inoculated into the rabbit through the sciatic nerve as well as through the anterior chamber of the eye. The virus does not seem to be pathogenic for monkeys when directly obtained from man, but becomes so after having passed a certain number of times through rabbits. It then becomes pathogenic likewise for guinea pigs. The virus retains its virulence after desiccation in vacuo in the presence of sulphuric acid and after desiccation in a watch glass in contact with caustic potash. The virus is present in the spinal cord of animals inoculated by the cerebral route. The serum of patients convalescent one month from lethargic and myoclonic encephalitis has no neutralizing action upon the virus. Experiments upon crossed immunity with the virus of poliomyelitis, upon vaccination of animals, and upon serum treatment are now being carried out.

The Oculocardiac Reflex in Lethargic Encephalitis.—A. Litvak (*Presse médicale*, February 14, 1920) states that in lethargic encephalitis the oculocardiac reflex is rather active. The more deeply somnolent the patient, the more readily the reflex is elicited. In syphilitic meningitis, this reflex is always absent, while in tuberculous meningitis it is only uncommonly present and is feeble. In lethargic encephalitis there may be observed a condition of dissociation between the tone of the circulatory centre, which may be lowered, and the oculocardiac reflex, which may be rather pronounced.

Syphilis and Lethargic Encephalitis.—E. Jeanseime (*Bulletin de l'Académie de médecine*, March 2, 1920) states that lethargic encephalitis may readily be overlooked in cases of suspected syphilis of the central nervous system. Many symptoms are common to both disorders, from dissociated paralysis of the cranial nerves and the Argyll-Robertson pupil to convulsive seizures and apoplectoid coma. The author's case was characterized by persistent somnolence from which the patient could readily be roused, complete mental clearness, and a diffuse paretic condition with motor incoordination reflecting cerebellar involvement. The tendon reflexes were markedly disturbed, ankle clonus was present,

and bulbar involvement was shown by tachycardia, dissociation of the pulse and temperature, and polypnea on slight exertion. Lumbar puncture at first showed 1.5 grams of albumin per litre, positive Bordet-Wassermann, and thirteen lymphocytes per cubic millimetre. Sixteen days later the lymphocytes had dropped to three and the albumin nearly to normal, and the Wassermann was negative. The blood Wassermann had been negative on two occasions. The initial positive cerebrospinal Wassermann is thought to have been due to the hyperalbuminosis. A positive reaction has already been occasionally noted in nonsyphilitic persons in the presence of marked hyperalbuminosis and xanthochromia of the cerebrospinal fluid.

Late Sequelæ of Lethargic Encephalitis.—Henri Claude (*Bulletin de l'Académie de médecine*, March 2, 1920) reports four cases illustrating the fact that encephalitis patients may continue for a long period after apparent recovery to be troubled with asthenia, inability to work, and the recurrence upon fatigue of particular symptoms, such as motor paresis, choreiform movements and visual disturbances. Altered disposition may also persist for some time. These sequelæ are explainable on the basis of the vascular and perivascular pathological changes found in cases studied postmortem.

Prognosis and Treatment of Epidemic Encephalitis.—J. Chalier (*Lyon médical*, April 25, 1920) estimates the mortality rate of lethargic encephalitis as forty to fifty per cent. Rise of the temperature to 40° C. is an unfavorable prognostic feature, as are also tachycardia—with or without fever—and polypnea, which suggest bulbar involvement. Cases manifesting excitement are more dangerous than those exhibiting somnolence alone. An unfavorable meaning attaches to the dissemination and progression of certain symptoms, such as myoclonic movements, particularly with participation of the diaphragm, and more or less diffuse choreic manifestations. Regarding treatment, Chalier considers the administration of serum from convalescents the most rational measure. In a recent severe case its use was followed by recovery.

Epidemic Encephalitis and Catatonic Symptoms.—Earl D. Bond (*American Journal of Insanity*, January, 1920), in a review of three cases found that mild and transient, but definite, symptoms are usually missed in excited, seclusive or indifferent patients. In one, strabismus went unrecognized at home; another, because she had no psychosis, was able to give information which would have been lost in a person less clear. Some facts came out in retrospective accounts which few can give satisfactorily. The author has elsewhere emphasized that fevers are usually overlooked in difficult and chronic patients. There is a great reward for the first hospital for mental diseases which can carry out good, thorough and repeated physical examinations on all its patients. A catatonic episode in a chronic mental patient demands and rewards the same skillful medical and nursing care which is given to the general hospital patient with acute encephalitis.

DIAGNOSIS AND TREATMENT OF HYPERTHYROIDISM.*

BY M. H. FUSSELL, M. D.,
Philadelphia.

The great difficulty in the treatment of many diseases is that we are constantly confronted with the end results of the disease, when the chances of bringing about a cure are almost nil. A patient with diphtheria who dies today does so because diphtheria antitoxin has either been used in too small doses, or used too late. Thousands of patients with tuberculosis present themselves with extensive disease of the lungs that can never be cured. Early diagnosis, which spells cure, has been missed.

Hyperthyroidism is frequently not diagnosed until the patient has all the characteristics described in the case quoted by Graves (1). He thus describes his case of exophthalmic goitre, said to be the first in the literature:

"A lady, aged twenty, became affected with some symptoms which were supposed to be hysterical. This occurred more than two years ago; her health previously had been good. After she had been in this nervous state about three months, it was observed that her pulse had become singularly rapid. This rapidity existed apparently without any cause and was constant, the pulse being never under 120, and often much higher. She next complained of weakness on exertion, and began to look pale and thin. Thus she continued for a year, but during this time she manifestly lost ground on the whole, the rapidity of the heart's action having never ceased. It was now observed that the eyes assumed a singular appearance, for the eyeballs were apparently enlarged, so that when she slept or tried to shut her eyes, the eyes were incapable of closing. When the eyes were open the white sclerotic could be seen to a breadth of several lines all round the cornea."

While it is true that many patients with well marked exophthalmic goitre recover under rest and other measures, it is equally true that every patient who has the marked characteristics of the disease has undergone a change in the heart muscle, and other organs of the body, which may cause death or prolonged invalidism. For this reason chiefly, I have selected hyperthyroidism for this paper, that we may discuss, first, early diagnosis and differential diagnosis and then treatment of the

condition in the early stages, and finally the treatment of cases in the later as well as the latest stages.

The symptoms of well developed exophthalmic goitre as described by Graves (1), and those which usually are described in textbooks are so striking that he who runs may read. Mental alertness, tachycardia, muscular tremor, exophthalmos, visible pulsation of the vessels, tumultuous action of the heart, sweating, warm hands and feet, frequently cardiac murmurs, enlarged, usually pulsating thyroid gland, tendency to flushing of the skin, an erythematous rash following handling of the skin, weakness, emaciation, diarrhea and vomiting, sometimes arthritis; all of these symptoms may be present in the advanced case of exophthalmic goitre, or Graves's disease. Of these, the protruding eyes, the appearance of fright, and the enlarged thyroid are the symptoms which attract the physician as the patient enters his examining room or even when he meets such a person on the street. We must always keep in mind the extreme cases of hyperthyroidism which may occur with little or no thyroid enlargement. Such a patient always has decreased sugar tolerance; unusual reaction to the injection of adrenalin; is made worse by taking preparations of the thyroid gland, and has an increased metabolic rate.

Unfortunately, many or all of the symptoms are present before active treatment is considered, either by the patient, or the examining physician. It is the patient in this condition, showing end results of the disease, who is in danger, and upon whom surgical operation is a serious procedure, and upon whom the recognized medical treatment is so frequently a failure. It is a condition fairly comparable to that of a patient in the second week of an active appendicitis.

A condition which is often indistinguishable from the one described, which demands somewhat the same treatment, occurs in the hypertrophic atoxic goitres, as described by Plummer (3).

Why do patients not present themselves for treatment before reaching this extreme condition? Why are they not treated sooner?

First, because patients consider themselves nervous, and delay treatment, or the physician to whom they apply in the early stage of the disease considers the patient as neurasthenic, as having an irritable heart, or heart disease, until the unmistakable signs of advanced Graves's disease, exophthalmic goitre, present themselves.

*The references to this article will appear in the reprint.

Thanks to the intensive studies of Charles Mayo, H. S. Plummer, Louis Wilson and Kendall (4), the condition of hyperthyroidism and other conditions due to disturbance of the thyroid gland, have been brought so prominently before the profession that we are beginning to realize the condition in its early stages, and hence the selected treatment is more effectual and less dangerous.

A short description of some of the later laboratory methods which help in the differentiation of these conditions, particularly in the early stage, seems desirable at this point. Hereafter they will be referred to as:

1. Increased metabolic rate; 2, thyroid feeding; 3, adrenalin test, Goetsch test, and 4, decreased sugar tolerance.

INCREASED METABOLIC RATE.

Dubois (5) in a paper on the Respiratory Calorimeter in Clinical Medicine says that the normal average basal metabolism is 34.7 calories an hour to the square metre of the surface of the body. He also states that in forty-four cases of exophthalmic goitre, the increase of metabolism is the most striking effect of thyroid activity, and is strictly proportionate to the activity of the disease.

Means and Aub (6) state that in 224 observations on toxic goitre, and eighteen cases of nontoxic goitre, the toxicity, judged clinically, runs nearly parallel with the rise in metabolism. I believe that the estimation of the metabolic rate of a patient is the most accurate laboratory method in differentiating mild cases of hyperthyroidism from conditions which simulate it. The great drawback at present to this valuable test is that it has to be made in an institution which possesses the proper apparatus for the work, hence it is not as practicable as the second test—thyroid feeding. The value of estimation of the metabolism test is shown in the following important case.

CASE I.—Mrs. L. This lady was sent for a diagnosis as to whether an evident goitre was the cause of her symptoms.

Her chief complaint was palpitation of the heart and throbbing of her neck, she had headache, was extremely nervous, had gained much weight. She was in the midst of her menopause; was extremely neurasthenic. She had had a goitre for several years. She had tremor and attacks of diarrhoea. Her weight was 205 pounds. There was an enlarged thyroid gland which was rather soft. Auscultation over the gland did not reveal pulsation or thrill or murmur. There was a slight tremor of her hands. Examination of her heart showed a rate of about 100. She was quite hysterical. Her blood count, except for a slight anemia, was normal, and the differential count was normal. Her blood pressure was 200 systolic and 110 diastolic. Her urine was normal. Her metabolic rate was twenty-seven calories to the cubic metre of her body. This latter fact caused the case to be classed as neurasthenia accompanying menopause, and not one of hyperthyroidism which it simulated. The subsequent history of the case showed this view to be correct.

THYROID FEEDING.

It is generally recognized that a person who is suffering from an increased activity of the thyroid gland will suffer an exacerbation of all of the symptoms when given desiccated thyroid gland.

Smith (20) used this test in the examination of thirty cases among soldiers at Fort Travis, Texas, with the idea of differentiating between this condition and the effort syndrome. Six of the patients responded to the test and were diagnosed upon this and upon other grounds as having hyperthyroidism. Lewis (10) believes that cases of effort syndrome are not due to hyperthyroidism and that use of thyroid feeding will differentiate between the conditions.

CASE II.—Several years ago Miss P. was seen with Dr. Merscher of Germantown, Pa. She had not been well for five or six years. Violent attacks of gastric pain, with much diarrhoea. Her pulse was 80 to 94. Blood pressure 135 diastolic and 180 systolic. The eyes were prominent; palpebral angle wide. The thyroid was enlarged. There was much muscular tremor. She was put upon thyroid feeding with an immediate exacerbation of her symptoms. In October, 1914, the upper pole of the right lobe of the thyroid was ligated. There was a temporary improvement. In January, 1915, the diarrhoea had disappeared, her weight was 118 pounds, there was much perspiration. On May 10, 1915, she was nervous, her weight was still 118. A ligation of the other lobe was done. A great improvement followed. On October 10, 1919, she weighed 134 pounds, was the picture of health, all signs of hyperthyroidism had disappeared.

Smith (20) describes a method of thyroid feeding as follows:

"The men were put to bed and isolated in one end of the ward. Other convalescent patients were instructed not to disturb them. The desiccated thyroid gland of sheep was used, Lilly preparation. The initial dose was one fourth grain morning and evening. This dose was increased one fourth grain each day and was continued until there was a response or the patient was getting five grains a day. The pulse was taken four times a day. The nurse was instructed to take the pulse whenever possible when the men were asleep. A definite increased pulse rate while the patient was asleep, associated with increased nervousness and irritability, was regarded as a positive reaction, and the thyroid feeding was discontinued.

THE GOETSCH ADRENALIN TEST.

This was described by Goetsch (7) in July, 1918.

"On the day of the test the patient is placed as nearly as possible under normal conditions. By this we mean in a warm room without the appliances such as hot water bottles, heating devices, which are common in the outdoor treatment of tuberculosis. The patient, of course, is to take his meals in bed. We emphasize these precautions because of the well known hypersensitiveness and irritability of hyperthyroid and tuberculous patients. Because of the tendency of the thyroid to hyperactivity at the menstrual period, the test is not given during this time.

"We proceed with the test as follows: Two readings are taken, at five minute intervals, of the blood pressure, systolic and diastolic, pulse rate and respiration. The notes are made of subjective and objective condition of the patient. This includes the state of the subjective nervous manifestations—the throbbing, heat and cold sensations, asthenia, and the objective signs such as pallor and flushing of the hands or feet, the size of the pupils, throbbing of the neck vessels, and precordial tremor, temperature of the hands and feet, perspiration and any other characteristic signs or symptoms noticed. These signs are all noted previous to the injection of the adrenalin, so that comparison may be made after the injection.

"A hypodermic syringe armed with a fine needle which, when inserted, causes little discomfort, is then used to inject 0.5 c. c. of the 1/1000 solution of adrenalin chloride into the deltoid region, subcutaneously. Intramuscular and intravenous injections are not given. Readings are then made every two and a half minutes for ten minutes, then every five minutes up to an hour, and then every ten minutes for a half hour longer. At the end of one and a half hours the reaction has usually entirely passed off, sometimes earlier. The repeated early readings are made in order not to miss certain reactions on the part of the pulse and blood pressure that may come on in less than five minutes after the injection is made. This is particularly true of cases of active hyperthyroidism.

"In a positive reaction there is usually an early rise in blood pressure and pulse of over ten points; there may be a rise of as much as fifty points or even more. In the course of from thirty to thirty-five minutes there is a moderate fall, then a second slight secondary rise, then a second fall to the normal in about one and a half hours. Along with these one sees an exaggeration of the clinical picture of hyperthyroidism brought out, especially the nervous manifestations. The particular symptoms of which the patient has complained are usually increased, and in addition there are brought out many symptoms which have been latent. Thus it is not uncommon to have extra systoles brought out after the injection of the adrenalin. The patient is usually aware of them, and may tell one that she has felt this same thing a year or two previously, at which time the symptoms of the disease were more active.

"The following may all or in part be found; increased tremor, apprehension, throbbing, asthenia, and in fact an increase of any of the symptoms of which the patient may have complained. Vasomotor changes may be present; namely, an early pallor of the face, lips and fingers, due to vasomotor constriction, to be followed in fifteen or thirty minutes by a stage of vasodilation with flushing and sweating. There may be a slight rise of temperature and a slight diuresis.

"In order to interpret a test as positive we have regarded it as necessary to have a majority of these signs and symptoms definitely brought out or increased."

From a review of the literature it would seem that this reaction is practically always present in

hyperthyroidism, but that it may occur in other conditions, noticeably in the effort syndrome. Peabody (13) and his coworkers examined sixty-five soldiers with irritable hearts by this method for the presence of hyperthyroidism, with a positive response to the test in sixty per cent. of the cases, a doubtful response in thirty per cent., and a negative response in ten per cent. That is, there was a positive result from the adrenalin test in sixty per cent. of the cases which did not show hyperthyroidism by other tests. Therefore, the adrenalin test is of less value than the metabolic rate or thyroid feeding. According to the article from which the abstract was made, however, the test is never positive in tuberculosis alone.

SUGAR TOLERANCE.

For a long time it has been known that patients with exophthalmic goitre had a low sugar tolerance. Harriman and Hirschman (8) and Wilder and Sansum believe that increase of thyroid function is accompanied by a decrease in sugar tolerance, and these authors in addition express the opinion that the hypodermic use of epinephrin is followed by a marked hyperglycemia—sugar will appear in the urine also after the Goetsch test. This test is of undoubted value, but like the adrenalin test is probably corroborative and not absolute.

Examination of the blood.—Kocher announced that the differential count was of considerable value in the differentiation of hyperthyroidism, while Plummer (11) in the tabulation of 578 cases of exophthalmic goitre, found that while the neurophiles are low and the lymphocytes high, the blood count is of relatively little value in diagnosis.

The conditions for which hyperthyroidism in any stage may be mistaken, or which may be mistaken for hyperthyroidism, are numerous. Among them are: 1, Neurasthenia; 2, irritable heart, or its synonyms, effort syndrome, functional papitation, 3, organic heart disease; 4, tuberculosis; 5, interstitial nephritis; 6, gastrointestinal disturbances; 7, arthritis; 8, local conditions of the eye, and 9, hypertrophic atoxic goitre.

Upon decision as to whether the patient is suffering from one or another of these conditions the treatment absolutely depends. A differentiation is therefore necessary. The limit of time which can be devoted to this paper will of necessity demand a rather superficial review. Enough will be attempted, however, to make the points intelligible.

DIFFERENTIATION OF HYPERTHYROIDISM.

Neurasthenia is constantly confused with hyperthyroidism. The most serious mistake is to consider a case of mild hyperthyroidism as a simple neurasthenia until the patient has Graves's disease in a well advanced form. The neurasthenic may have muscular tremor even when the arm is held horizontally with the fingers spread apart, but this tremor is intermittent, and is not continuous as in hyperthyroidism.

The mental characteristic of the neurasthenic is an introspective one, and not the alert apprehensive mind of the hyperthyroid patient. The neurasthenic does not have the flushing characteristic of disease of the thyroid.

The rapid heart of the neurasthenic frequently becomes slower when the patient is recumbent for a short time, as opposed to the continuous tachycardia of the hyperthyroid patient. The heart is not dilated in the neurasthenic individual as it is in the moderate or advanced hyperthyroid patient.

The thyroid of the neurasthenic if enlarged may pulsate, but the pulsation is evidently transmitted from the vessels below the gland is not the seat of a murmur, or a thrill. The eyes do not protrude, and there are none of the other characteristic eye symptoms.

Increased appetite is a characteristic of hyperthyroidism (14); the neurasthenic usually has a loss of appetite. Finally, the neurasthenic does not respond to thyroid feeding; the metabolic rate is not increased; the Goetsch test is not positive, and sugar tolerance is normal.

Irritable heart.—This is a condition frequently seen in civil practice, and was first described by Da Costa. It was very frequently noticed in examination of draftees by draft boards and by the cardiac boards of the army, 1917-18. It is characterized by the inability to withstand exertion, by tachycardia which is increased by exercise, by a soft murmur over the apex or the base, which may disappear on exercise, and by muscular tremor.

These symptoms notoriously resemble those of hyperthyroidism, but the eye symptoms of exophthalmic goitre are wanting, the thyroid gland is normal, or if hypertrophied is not the seat of intrinsic pulsation or thrill. There is no erythematous rash. The laboratory signs of thyroid feeding and increased metabolism rate are wanting, while the adrenalin test may be present in sixty per cent. of the cases (13), and the sugar tolerance test is negative except in rare instances (3).

Organic heart disease, particularly mitral stenosis, is frequently mistaken for hyperthyroidism, and the opposite mistake is often made. Close attention to the actual condition of the heart, the presence of a confirmed murmur due to endocarditis, the characteristic murmur of mitral stenosis, the fact that the rate of the rapid heart of organic heart disease is reduced upon rest, the absence of the peculiar alertness of hyperthyroidism with its wavelike exacerbation (14), the absence of the eye symptoms, the negative findings in the four laboratory tests, mark the case as one of organic valvular disease.

Myocarditis in older persons may also be mistaken for hyperthyroidism, but attention to the actual condition of the heart, and the absence of characteristic symptoms of hyperthyroidism, will mark the case.

The following case shows the difficulties sometimes encountered in making the diagnosis.

CASE II.—Mrs. G. S., wife of physician, seen March 14, 1918. Felt weak, no cough, no dyspnea, but palpitation of the heart, nervous spells, vomiting in the morning, bowels rather loose, much worried, marked taché, no exophthalmos or other eye signs. There was some tremor of the hands. The thyroid was decidedly enlarged, but there was no pulsation or thrill. The heart dullness reached to one inch to the right of the sternum, the nipple line, and the upper third rib. There was a suspicion of a

presystolic murmur. On rest in bed the heart dullness decreased, the presystolic murmur became very evident, the thyroid gland decreased in size. The progress of the case marked it as a true mitral stenosis, notwithstanding the first appearance of exophthalmic goitre.

Tuberculosis.—Symptoms indicative of hyperthyroidism may frequently complicate certain cases of frank tuberculosis, or cases in which there is a suspicion of tuberculosis, but in which the physical signs are not marked. Of course the physical examination and history of the case must be the sheet anchors in making a diagnosis, but it is these borderline cases in which Goetsch (7) claims so much for his test. He says: "It should be mentioned furthermore that the adrenalin hypersensitivity reaction affords us a means of early diagnosis of hyperthyroidism at a stage before the disease has seriously damaged the individual or perhaps incapacitated him. It thus allows us to appreciate an early mild hyperthyroid element in tuberculosis should the two diseases exist concomitantly."

It is in these cases also that thyroid feeding and metabolic rate should be of greatest value.

Interstitial nephritis.—Barker (15) described the presence of exophthalmos in interstitial nephritis, and calls attention to the danger of mistaking certain cases of nephritis for hyperthyroidism. The constant high blood pressure, polyuria and urinary findings, and the absence of findings of hyperthyroidism other than the eye symptoms, and the negative findings, should make the diagnosis simple.

Gastrointestinal conditions.—In rare cases of hyperthyroidism, the outstanding symptom of the disease, is diarrhea. The following case illustrates this condition in a typical way.

CASE III.—Mrs. W. For years had an intractable diarrhea. She appeared for treatment August 26, 1909, with the following complaints:

Diarrhea for three years, eight to ten bowel movements a day; lost thirteen pounds in two years; always nervous; some palpitation of the heart and some dyspnea. There was a large cystic goitre. The second pulmonary sound was accentuated. At this time the goitre was not considered in relation to her diarrhea.

On May 3, 1913, she returned with evident signs of a toxic goitre, including diarrhea and arthritis. Her elbows, shoulders, hands and feet had been intermittently painful and swollen during the existence of the goitre. Since the removal of the goitre five years ago the joint pains have disappeared and never returned.

Her goitre was removed with no untoward results, and the condition of the patient immediately improved—the diarrhea and arthritis disappeared. In 1919 she reappeared at the office having gained thirty pounds and was the picture of health.

Arthritis.—I am not aware that arthritis has ever been considered as a symptom of hyperthyroidism, but in the case of Mrs. W. and Mrs. T. whose history follows, in both instances the arthritis disappeared with the removal of the thyroid gland. Whether this was a mere coincidence I am not certain, but the facts are accurate, and I wish to put

them on record. Unfortunately there is no note as to any of the laboratory methods, and therefore one cannot express a positive opinion as to whether the hyperthyroidism which existed intermittently was the cause of the arthritis. Certainly, however, the arthritis disappeared upon the removal of the gland.

CASE IV.—Mrs. T., aged thirty, was examined by Dr. Corson of Cynwyd, January 15, 1915. When she was thirteen years of age a goitre developed with toxic symptoms. This attack of hyperthyroidism disappeared, to reappear three times in the last seventeen years. For the past twelve years she has had painful, enlarged joints in various parts of the body; for the last five years these were much worse, until now she is an invalid from the painful joints, arthritis or peri-arthritis.

On examination she had a large goitre which apparently was not toxic unless her arthritis was an indication of toxicity. Her joints are the seat of swelling, pain and stiffness. She was seen by Dr. Halstead, of Baltimore, and her thyroid was removed. I based the reason for the operation on the fact that Mrs. W. who had had arthritis and hyperthyroidism was cured of the arthritis after thyroidectomy.

A letter from her physician dated December 4, 1919, states that since her thyroidectomy she was completely relieved of her arthritis and muscular pains, which she had continuously for twelve years.

Local conditions of the eye giving rise to exophthalmos.—Such conditions might, of course, give rise to the appearance of hyperthyroidism, but the entire absence of other signs would negative that diagnosis.

Hypertrophic atoxic goitre.—Whenever a case of simple hypertrophic goitre presents itself, the question as to its toxic character must always be taken into consideration. An atoxic goitre is entirely void of all of the symptoms of hyperthyroidism. The fact that in the patient there may later develop toxic symptoms, so well described by Dr. H. S. Plummer, must always be taken into consideration.

As a diagnostic sign between a hypertrophic atoxic goitre in which there develops toxic symptoms, and a toxic hyperplastic goitre, true Graves's disease, H. S. Plummer cites figures to show that the hypertrophic goitre develops symptoms after an interval of fourteen and a half years, while the true exophthalmic goitre is observed only nine tenths of a year before the toxic symptoms (13).

It will be seen that while there are a number of conditions which simulate hyperthyroidism the chief difficulties in differentiation occur in the early stages. It is scarcely possible to mistake a well developed case of exophthalmic goitre for any other condition, and the opposite mistake is likewise unlikely to occur. It therefore is important that all of us have in our minds the possibility of making mistakes in the early stages, and do all we can to avoid them. The laboratory methods which have been described are of the utmost value in differentiating difficult cases, especially the metabolic rate which is always increased in exophthalmic goitre.

TREATMENT.

Unfortunately the ultimate cause of hyperthyroidism is not yet certain. The researches of Can-

non (16) and Wilson (17) point to some irritation of the sympathetic as the possible actual cause. Certainly Cannon has proved that the nerve supply of the thyroid is from the sympathetic, and Wilson has found that "certain bacteria may cause histological pictures in the sympathetic ganglia and in the thyroid gland which parallel those found in progressive and regressive exophthalmic goitre."

For these reasons, and due to the fact that we are attributing many general conditions to local infections (frequently I believe without sufficient grounds, especially many teeth and numerous tonsils are removed without sufficient grounds), the search for tooth abscesses, infected foci in tonsils, and other localities should be made. If found they should be corrected in order that we may do possible good, and in order that we may not later accuse ourselves of negligence.

Kendall's (2) epoch making investigations appear to prove that the iodine containing compound, thyroxin, is the positive cause of the toxic symptoms found in hyperthyroidism, whether it is that of true exophthalmic goitre, or the toxic symptoms in cases of hypertrophic atoxic goitre. Hence measures both medical and surgical which will prevent the increase and absorption of this substance must be adopted.

Perhaps it is the uncertainty of the cause which causes so many and often opposite views as to method of treatment. Still more likely the different methods of treatment may be due to the fact that in many cases of hyperthyroidism, and even in some cases of well developed exophthalmic goitre the symptoms disappear and the patients entirely recover without any accurately directed treatment. Whatever methods have been used in these cases are heralded as a cure.

The positive knowledge which we now possess that the iodine containing compound, thyroxin, is the cause of the toxic symptoms (18) puts us on firm ground from which we may direct our treatment, for whatever the cause of the hypersecretion of this substance, we know that long continued secretion will lead to invalidism and death.

The problem then is, what is the best treatment for the condition of hyperthyroidism? Discussion of this most important phase of the subject must include the so-called medical treatment, surgery, röntgen ray, and injection methods.

The physician who recognizes that there is no one plan of treatment for all patients, is the safest one for the patient, because he is the one most likely to bring about a cure of the condition. Some patients are fit for one kind of treatment alone, others demand the combination of two or more forms of treatment. The knowledge and ability to select the proper patient for a special treatment or combination of treatments is the acme of attainment. Each one of us must bring all the knowledge we have to bear upon each case. A careful study should be made of each case and all of the possibilities considered.

The subject of treatment is best considered by including hypertrophic atoxic goitre or simple colloid goitre, and thyroid enlargement common at the age of puberty, with that of toxic goitres.

HYPERTROPHIC ATOXIC GOITRES.

Much discussion of this subject has taken place. The use of iodine in minute doses has been recommended, and other drugs without number, but in my opinion, based on experience and upon the literature, surgery is the treatment of choice of non-toxic, long standing goitres. Certainly all goitres which are increasing in size, all which have not responded to small doses of iodide of potassium, one grain three times a day, all which are giving pressure symptoms, all which are the seat of tumors, should be removed. As one reason for removing all large goitres, Balfour's statistics may be quoted.

Cancer of the thyroid according to Balfour (19) occurred in 103 cases of 6,359 cases operated in the Mayo Clinics, with a mortality of six per cent. from operation, forty-seven and six tenths per cent. early recurrence, eleven per cent. are living, a total of sixty-five and six tenths per cent. This arbitrary view from an internist comes from the practical lack of mortality in operation of simple goitres, and the decided risk of toxic symptoms and malignancy in long standing simple goitres, as well as the decided uselessness of any medical treatment with which he is familiar.

GOITRES WHICH APPEAR AT PUBERTY.

These patients should be given either small doses of iodide or let alone, as in the experience of everyone those enlargements usually disappear as the person becomes older. Of course if the goitres become toxic or undergo changes which render them dangerous, they should be removed.

HYPERTHYROIDISM AND EXOPHTHALMIC GOITRES.

Four methods of treatment will be discussed: First, rest; second, röntgen ray; third, surgery; fourth, injection methods.

Means and Aub (6) have made some useful observations on the influence of the metabolism rate by single and combined treatments of the above methods. Their conclusions are: a, rest alone usually causes a marked decrease in toxicity; b, drugs in addition to rest do not materially accelerate the decrease of toxicity; c, the röntgen ray in some cases produces a decided improvement, while in others it has no effect; d, the usual immediate effect of surgery is a marked decrease of toxicity but there is a very definite tendency to recurrence.

Rest.—All patients with mild hyperthyroidism should at once be put upon rest treatment. This should as nearly as possible approach in detail the principles long since recommended by Weir Mitchell for neurasthenia. The patient must be away from home, in bed, in the hands of a competent nurse, and be given superalimentation. The treatment at home cannot be considered except as a makeshift. The father or mother cannot possibly separate themselves from their many worries when surrounded by familiar scenes and sounds. The ordinary medical ward must also be considered a makeshift, as pointed out by Alfred Stengel in a discussion at a recent meeting of the Medical Session of the College of Physicians of Philadelphia.

Many of the patients with beginning hyperthyroidism will respond to a properly conducted rest treatment, and will go on to complete cure. Re-

sponse occurs occasionally even with the makeshift trials.

The rest is particularly important in cases which occur as the apparent result of extreme fright, excitement and nervous strain. The removal of these apparent exciting causes in certain cases of Graves's disease will often be all that is necessary to bring about a cure. Rest is also imperative in the very toxic cases before thought of operation is entertained.

The following case is an example of what rest and change of surroundings will do.

CASE V.—Mrs. M. B., New York, on September 11, 1914, complained of diarrhea without assignable cause. There was no abnormality of the heart, blood vessels or thyroid. During March, 1915, she complained of cardiac palpitation and some tremor. The heart's action was tumultuous. There was no enlargement of the thyroid. The next week the tumultuous action of the heart with tremor of the hands was still present. During July, 1915, she had much less tremor and cardiac palpitation. For the first time, the enlargement of the thyroid was noticed. Before this the true character of the disease was not recognized. Her eyes were prominent. There was a tremor of the hands, fullness of the thyroid, which pulsated and was the seat of a to and fro murmur. The heart was enlarged to the left.

She was sent away from the family to Atlantic City and kept at rest, and belladonna was administered. In two months she was much improved. The neck had decreased four centimetres in circumference. Five months later (after seven months at the seaside) there was no cardiac palpitation, the pulse was 88 and she had gained twelve pounds in weight. There were no signs of the exophthalmos which was so prominent in July, 1915.

It will be seen that in this patient after the use of belladonna and her separation from all her former surroundings, all the symptoms disappeared. On January 5, 1920, her husband reported her as entirely well.

Of drugs, belladonna given in full doses to the physiological limit, bromide of potassium in ten to fifteen grain doses three times a day to quiet the patient, veronal at night the first few days to procure sleep, and morphine hypodermically in patients who are highly toxic, are helpful and often efficient. But the use of this method of rest and drugs must not be persisted in if the symptoms are not distinctly ameliorated after a period of observation, differing in each case. Surely surgery must be used if the patient does not improve in a few weeks. The patient should not be allowed to drag on in a condition of no improvement.

Charles Mayo repeatedly calls attention to the fact that the operation for toxic goitre is not an emergency one. We all know that the chief danger in surgery in hypothyroidism is in its employment in patients who are highly toxic. We are also aware that before surgery is employed in patients with very toxic goitres, the metabolism rate must be reduced by rest, drug treatment, and possibly by the use of the röntgen ray.

Without personal experience in the use of x ray,

but basing my opinion on the work of Pfahler, Pancoast and Manges, I believe that in selected cases of great toxicity, and in patients suitable for surgery, but who will not submit to this treatment, the röntgen ray will be of use if it is applied by an expert but it is highly dangerous if not applied according to well known safeguards. Not every man who runs an x ray machine is competent to treat toxic goitres, any more than every man who can wield a scalpel is competent to ligate the vessels or resect a thyroid gland affected by thyroid hyperactivity.

I am not a surgeon, and hence cannot give any direct advice as to how to do a thyroid operation. But being an internist I can have an opinion as to which operations have been of the greatest value to my patients. First as to the method of Crile in the use of anociassociation.

I have seen patients treated by the expert use of this method at the hands of Dr. Charles Frazier, have the thyroid resected or the vessels ligated and the patient leave the hospital without the knowledge that an operation had been performed. Surely a method which will relieve the patient of the worry, the fright, and the distress caused by the thought of an operation, is of the greatest value. It fails in the hands of many because the surgeon does not realize or carry out the necessary details.

In every severely toxic case, the patient must be given a thorough rest cure, with proper drugs, and perhaps the use of the x ray until the patient is as much improved as possible. Even ligation, as usually performed, is sometimes dangerous. I have seen severe exacerbation and occasionally death follow ligation.

The following technic is described by Charles Mayo (21) and is quoted as the best and usual method:

"Greater operative experience upon cases of hyperthyroidism has led to a great reduction in mortality. This has come about through many changes in the earlier operation, better operative technic, more careful preparation of the patients, choosing the operation to suit the case, and the graduated operation.

"*Operation.*—A transverse incision gives the best working space as well as the least disfiguring scar. It is made two and a half inches in length, crossing the central part of the thyroid cartilage. The incision should be made in a natural skin crease if possible, and should include the platysma myoides, this one incision being better than two lateral ones. The inner border of the sternomastoid is tracted laterally. This exposes the omohyoid muscle which is tracted up and in toward the midline. Beneath this muscle is the upper pole of the gland with the superior thyroid artery and vein.

"The ligating material is linen passed by an aneurysm needle. Should a vein be pierced and a hemorrhage follow the placing of the ligature, it is tracted upon and a second loop is passed around including more tissue."

There are certain patients who are so desperately ill that surgical intervention is full of danger, but where a delay seems certainly fatal. Dr. A. C. Wood has performed the operation of ligation un-

der such conditions with the result of great improvement, allowing later on a partial thyroidectomy and the cure of the patient.

I have had Dr. Wood put down his method. His note I quote in full:

"Assuming a condition of extreme thyroidism in which medical measures have failed to relieve the urgent symptoms, and in which it is necessary to promptly reduce the thyroid activity, the control in the circulation of the gland suggests itself as one of the most promising measures. This can be accomplished by ligating one or more of the four principal arteries supplying the gland. It is usually advisable to tie one or both superior thyroid vessels, as they are more accessible. The operation is a simple one, and may easily be done with local anesthesia. A two inch incision along the anterior border of the sternocleidomastoid muscle, through skin and platysma, exposes the muscle. The deep fascia is incised in the same line, the sternomastoid gently retracted outward, which exposes the sheath of the great vessels. The sheath is opened and the vessel sought is readily found just above the bifurcation of the common carotid artery. The ligature should be of thread rather than of catgut.

"In many cases not a single vessel is divided that needs a ligature, and it is rarely necessary to tie more than one or two bleeding points. No drainage is required.

"This technic may be carried out without the least trauma or interference with the thyroid gland, without any general anesthesia, and hence without adding any additional burden to the load the patient is already struggling with. If both vessels have been tied, the blood supply to the gland has been reduced by half. In the most extreme cases, it may be desirable to ligate but one vessel at a time."

So many modifications of the original suggestion of arresting a part of the blood supply to the gland have been made and carried out, that one reading the literature might be in doubt as to just what is intended by the term ligation.

The following case illustrates the extreme illness of some of these patients, in which any increase of metabolism would seem to be quickly fatal, and in which the method of ligation employed by Wood is highly advantageous. It is just such cases or even less dangerous ones in which x ray may be used.

CASE VI.—Mrs. C., aged thirty-five. Seen with Dr. W., Hightstown, N. J., July 18, 1919. For many years she had recognized a goitre which had given her no trouble except from its appearance and size. There was no pulsation inherent in the gland and there was no murmur except as transmitted. Marked exophthalmos, was present; the pulse was 135; heart dilated and a murmur over the body of the heart; blood pressure 160 and 80. Seen December, 1915, there was distinct loss of health, dyspnea, pulsation of the vessels, and palpitation of the heart. On July 14, 1918, there was sudden severe vomiting, diarrhea and rapid emaciation. The patient seemed at death's door. She was put on more strict rules of rest, a nurse was obtained, but the symptoms gradually increased in severity. At the end of this period, Dr. Wood tied both superior thyroid arteries with almost imme-

diate improvement. In six months there was a return of the symptoms of hyperthyroidism. The right lobe and isthmus were removed. Since then the patient has regained her health.

As to the question of choice between ligation and resection. The rule that seems best is first ligation of one or both arteries in every severe case, then ligation of the pole, then a partial resection. It is better to do too little than too much. A second operation can be done. A patient cannot be recalled from the grave.

INJECTION METHODS.

I have not had experience with these methods, but with access to certain methods of surgery, injection seems cumbersome and uncertain. The following succinct plan may be followed in treating hyperthyroidism with the minimum of fatality:

First. An early diagnosis is imperative by the methods here detailed.

Second. Every patient should be put to rest in order to reduce the metabolism rate. Many patients will be cured by this means.

Third. Patients who cannot give the time to a thorough trial of rest should be operated upon early, after a partial rest.

Fourth. Patients who are very toxic must always be put at rest and given other appropriate treatment before any form of surgery is attempted.

Fifth. If patients fail to improve under rest, ligation should be done, or the röntgen ray should be used tentatively to reduce the metabolism rate, until a resection can be done.

Sixth. In very severe cases in which the patients appear to be approaching death, and the x ray cannot be used, a ligation after the method of Wood may be done.

The writer thoroughly believes that in patients who do not promptly respond to rest, surgery by all odds is the proper procedure.

INDUSTRIAL MEDICINE.*

Its Proper Relation to Industry.

By S. DANA HUBBARD, M. D.
New York.

Fundamentally, the science of medicine is applicable to industry, for its principles may be applied to the selection and assignment of applicants for work, to the supervision of laborers when at work, that they may produce with greatest effectiveness and with least harm to the individual worker. Labor may be controlled scientifically; the principles of the prevention of accidents and of illnesses may be practically applied, so that production may not be diminished by injury unnecessarily inflicted upon workers or these laborers made ill and unable to work, thereby causing loss of time, waste of material in the raw product and unnecessary expense to the producer.

Industrial medicine in practical application must naturally be a compromise between the ideal and the commonplace, the medical ideal being that medical service in industry to be of the greatest possible usefulness must primarily benefit the worker and

through increased capacity, ability and usefulness react to the benefit of industry and through these to public health. The policy of good management is to assist workers to the greatest possible degree of production, and to do this successfully workers must be selected, assigned, tried out, intensively trained, and compared so that those best suited may be employed. Once employed their work should be supervised in order that they may continue to perform the maximum of work with the least possible wear, much the same as does the machine when properly adjusted and working at its highest efficiency under intelligent supervision.

THE DUTY OF EMPLOYER TO HIS EMPLOYEES.

Generally speaking, it is the duty of the management to provide for the worker the following essentials: 1, A safe, healthy place in which to work and which is kept clean and well ventilated; 2, tools, machinery, and methods which permit of rapid work of good quality; 3, careful, competent and helpful supervision; 4, if work is monotonous, exhausting, or requires concentration, time for rest and recreation; 5, opportunities for education and advancement; 6, fair and adequate wages with regular payments; 7, medical and nursing supervision, with instruction on how to keep well and avoid injuries; 8, special facilities for training inexperienced workmen; 9, reduction of all hazards to the minimum; 10, encouragement of thrift, domesticity, morality, and sobriety. The fulfillment of these duties makes employers expect that their workers will be healthier, happier, their services more stable, and production at the maximum of capacity. These results are beneficial to the worker, to the manufacturer and to the public.

THE DUTY OF THE EMPLOYEE TOWARDS HIS EMPLOYER

1, That he shall be interested and enthusiastic about his job; 2, that he shall be loyal to his work and exert every possible effort to have others so; 3, that he shall give a full day's labor for a day's pay; 4, that he shall conserve material, prevent waste, be honest, and play fair; 5, that he shall report dangers of all kinds, whether it is his duty or the duty of another; 6, that he shall take due precaution to aid his fellow worker and prevent sickness or accident; 7, that he shall willingly and cheerfully cooperate best to serve his employer and aid his fellow workers.

HEALTH AND INDUSTRY.

Employers are beginning to realize that the subject of health vitally concerns their industrial problems. Industrial medical and surgical supervision of work is essential in order to produce efficiently, as capacity depends probably more largely on the physical and mental condition of the workmen than on any one single factor. To reduce hazards, especially those which occasion illness or injury, requires medical attention. If we are to secure and maintain high efficiency in a working force both health and safety must receive necessary and proper consideration.

The first step in the conservation of energy and health is to learn the facts of the physical condition of the workmen. False modesty and sham must be turned aside and those industrially employed taught

*Read before the Academy of Pathological Science, New York, April 23, 1920.

how to live good clean lives, employers must be taught the error of overdriving workers to the point of exhaustion, the public made to stop exploiting labor, and profiteering eliminated.

THE FACTOR OF PREVENTION AND EDUCATION.

Individual plants often have accidents which cost both money and lives. Many of these manufacturers are indifferent because they are protected from loss by insurance. The man who is ignorant of the cause of these conditions thinks that by posting bulletins he may remove the cause. He hopes that people will remember his words and their safety but he permits the hazards to remain instead of accepting the principle, "Conditions shall be such that workmen may pursue safely their normal activities without abnormal care." There is no use talking in high brow phrases and then neglecting essentials. The wise and prudent man knows what are the prolific causes of both sickness and accident and governs his actions accordingly. Workmen are, as a rule, unaware of these and it is necessary that they be apprised by repeated cautioning, by careful education and by proper protection.

THE INDUSTRIAL MEDICAL OFFICER.

To reiterate, medical aid almost specifically concerns industry. It is not sufficient simply to have a dispensary in the plant with hours for advising or treating such employees as may from time to time need medical advice, or to have first aid applied. Industrial medicine demands not only a knowledge of the human body, a knowledge of the conditions which impair it, as well as the means for restoration when impaired, but also the more necessary measures that will enable workmen to reach and maintain their greatest capacities for good work. The ability of medical officers to participate in this plan establishes the logical relation of medicine to industry.

Since the value of medical service will be measured by its effect on production, the most useful industrial medical departments are those best able to avoid accident and prevent absence incident to illness which means, loss of time, unnecessary expense to both management and worker, as well as increased labor turnover, diminished production, and in frequent instances waste of material. The human element must be known and evaluated. The long way is the safe way, but it is the short way which usually is taken and is the dangerous way because human nature loves to take a chance. Managements and labor both seem today to object to the long way. If time is so essential a factor that the long way must be sacrificed, how can labor be speeded up without actually occasioning a breakdown or heating up of the human mechanism?

This is the problem of the medical officer of the plant. A man applies for the position of watchman. This applicant has flat feet, but no physical examination is made and so every one, even the applicant himself, is unaware of the defect. In time, however, he finds walking painful and instead of walking and watching, he sits and eases himself, neglecting his duty, and giving opportunity for depredation by thieves with attending loss of property. This is the forbidden way and the inevitable happens. The workman's neglect is discovered and he is discharged,

which is like locking the stable door after the horse has been stolen. Had the defect been remedied in the first place a man would not have lost his job, labor turnover would have been reduced, and property would not have been lost. Is not this contributory negligence on the part of the management? Can such management be considered efficient? To ascertain the presence of defects, in order that employment departments may know the limitations of employees, is a true function of the industrial medical officer.

Monotonous, concentrative or exhausting operations are known to be hazardous to health. Who appreciates this better than does the medical officer, and who is there to detect this physical stress and resulting inefficiency better than the plant physician? If no physician is employed or if one is employed who does not appreciate his position, there is none to aid the management in stopping this costly leak to production.

The plant physician comes into intimate contact with almost every branch of the industry, more especially with the employment office and the divisions of medicine, safety and welfare. If the plant physician is efficient, he fulfills the various demands made upon him. He needs must know intimately and well the workings of each branch of the plant and by making physical examinations and periodical reexaminations of the workers, and supervising the sanitation of the plant, he can exert a direct influence upon the essential elements of production. If he examines applicants for employment he uses the knowledge obtained for proper placement with regard to capacity and fitness. The perfect man is not to be found, but with medical guidance the man with defects may be guided and directed so that he may serve most efficiently and with the least harm to himself. The plant physician attending accident cases and investigating the causes leading up to them is in a position to recommend measures to prevent the repetition of such incidents.

If the plant physician has the proper idea of medical supervision of industry, he attends the sick workmen at their homes and becomes familiar with their domestic and community problems. He knows whether this workman or that is spending his earnings wisely; whether this man is rearing his family so as to be an asset to the community; which one is thrifty and is looking ahead and preparing for the proverbial rainy day, or whether in a more or less short time another liability will be thrust upon society. Through the careful plant physician the problem of communicable diseases may be studied and their introduction into the plant, with the ensuing disastrous effects upon production, loss of time, and waste of material, may be prevented.

By proper use of the plant physician, the worker is adapted to his job, accidents are prevented, sickness is diminished, absence reduced, labor turnover minimized and the workman made to feel that there is some one influential with the management interested in his personal welfare. This raises morale and increases interest in the work. A full knowledge of the physical and temperamental limitations of the worker is of much assistance to managements and in all instances of direct benefit

to the worker himself. Does the ordinary plant apply this knowledge to the aid of production? Only in exceptional instances is this done. Why? Has not the misuse of the physician as an eliminator of bad material or improper use of the plant physician made labor distrustful of a service that when properly used is labor's greatest aid to efficiency and health? No doubt the contract doctor with his limitation of service and abilities has also had a bad if not actually a vicious influence which has resulted in much misinformation regarding industrial medical service.

The modern industrial physician knows under what conditions people may engage in hazardous occupations and what precautions are essential to both safety and health. He instructs his aids, drills his staff, and informs his workers so that when danger appears or accidents occur the medical service is prepared and acts promptly. Industrial physicians meet many opportunities to clear up differences between employer and employee and even among employees themselves. By successfully availing themselves of the opportunities afforded by a modern industrial medical service, managements know intimately the physical limitations of their industrial staff. Without this information some are overworked and others are underworked.

NECESSITY FOR MEDICAL GUIDANCE IN INDUSTRY.

Statistics regarding health in industry are replete with interesting correlating facts. From the United States Department of Labor we learn that there are about forty million people engaged in industry. Of this army of workmen there are about 750,000 who sustain accidents which disable them for a period of more than four weeks' duration. There are about 22,500 industrial workers killed annually, and between 15,000 and 18,000 who suffer permanent disability. The economic waste from these accidents means the loss of working time of over 60,000 laborers or 18,000,000 work days a year.

Sickness in industry likewise exacts a heavy toll. We are informed from the same source that the average worker loses about nine days a year. This means a loss of one million workers a year or 360,000,000 days a year, both of which estimated at an average per diem wage means a stupendous amount in dollars and cents. This is the loss simply from sickness and accident: to this there must be added the loss of production, the cost of medical and nursing service and medical supplies, and sundry expenses which make a sum running into the billions. There is no greater problem before the country today than that of caring for the industrial worker. There is no one in this country who can better cope with this situation than the properly trained and equipped industrial physician.

AIMS OF INDUSTRIAL MEDICINE.

1. Devising ways and means of improving the health of workmen; 2, preventing losses to employers due to the poor health of employees; 3, preventing losses to employees due to their own poor health; 4, demonstrating the advantages of health supervision; 5, preventing sickness, accidents, and deaths incident to poor health; 6, removing hazards which occasion poor health or cause injuries to workmen.

APPLICATION OF INDUSTRIAL MEDICAL SUPERVISION.

1. Plan a daily program so that there will be a healthful balance between work and outdoor activities; 2, develop habits of cleanliness in person, food, dress and environment; 3, instruction so that there will be intelligent cooperation, hygienic rules carried out willingly, at work, in the home, and in the community; 4, education as to the necessity of appreciating early signs of illness and of seeking medical assistance; 5, preserving eyesight, demonstrating proper and improper lighting, avoidance of glare and direct light ray irritation, protective devices; 6, teaching the employed what is a suitable and well balanced diet; advice concerning luncheons, and meals generally; meeting the physical needs of diet; 7, avoidance of exposure to heat or cold, getting wet, chilled, cooling off too rapidly, dressing to meet weather conditions; 8, cleanliness, necessity of clean clothing, clean and safe work garments, bathing, washing hands, clean habits; necessity for cleanliness about children to avoid sickness in the home and escape the stress and strain of home worries; 9, vermin, the cause, the dangers; characters of vermin and destruction of such pests; 10, precautions to be observed regarding the communicable diseases; 11, necessity for rest, recreation, days of rest, taking time to eat and resting after meals; amount of sleep required; signs of fatigue, of debility, loss of flesh, and too early advancing age; 12, avoidance of excesses, what constitute excesses; dangers of over indulgence in sweets, tea or coffee, drinks, excessive smoking, late hours; 13, necessity for the use of safe, strong, suitable tools, ladders and protecting devices; 14, keeping articles out of the mouth; necessity for keeping fingers out of ears, nose, mouth, etc.; 15, necessity for safe and sane habits about shop; the need for looking out not only for self but exercising consideration for others in regard to yards, toilets, sinks, urinals; keeping aisles clear and unobstructed.

Industrial strength equals the sum of individual physical efficiency. Every person employed in an industrial plant is a determining factor in the strength and efficiency of production. Success is not determined by the brains and physical energy of the management but by the earnest zealous enthusiasm of every individual employed in the works. The field therefore of industrial medicine is limitless. Enthusiasm for the job depends upon proper adaptation of man to work and the participation of that man in the requirements of his work.

There must be working enthusiasm—there must be a desire for health—if there is it will do much to give the worker strength, virility, and above all a reason to live. No factor in living is so important as health.

Actually to enjoy life, we must be free from the burden of poverty and sickness as well as free from the fear of future want and be able to appreciate the present good. The problem of industrial medicine is how can we make men eager to work and eager to live. We must teach them how to take proper care of themselves and make the most of their opportunities. Brains are paid for and command a ready market.

THE CONDITION OF THE CHEST IN INFLUENZA.*

Surgical Aspect.

By L. J. HAMMOND, M. D.
Philadelphia.

The surgical phase of postinfluenzal chest conditions lends itself mainly to a discussion of thoracic effusions. These are primary in only a limited number of instances, the vast majority of them being secondary, occurring either as part of the clinical picture of some general infection, such as was so commonly met with during the epidemic, or an extension of local processes in neighboring organs, especially those affecting the lungs. And yet, while secondary, the physiological conditions that exist in the thoracic cavity are such that an independent clinical picture is produced by the effusion, requiring special treatment not independent of, but in conjunction with, the medical treatment. The effusions that occurred during the epidemic of 1918 were exceptional only in that they were, more often than is usual, sudden in occurrence and massive in quantity, and associated frequently with extensive effusion into other serous cavities.

The more usual occurrence of these effusions is late, during the period of recovery from inflammatory disease of other organs. All pathological effusions demand special treatment independent of the primary disease, hence it becomes at once of special surgical interest. The effusions differ greatly both as to extent and characteristics and may be anything from a mere transudate, a clear serous exudate, a cloudy exudate, on through transitions to pure pus, serohemorrhagic fluid, pure blood and chyle. The mere presence of effusions in sufficient quantity causes disturbance of respiration and circulation proportionate to the quantity, and the systemic disturbance is directly dependent on the virulence of its toxicity by absorption of the invading organisms. Not all serous effusions, however, have toxicity. Even during the epidemic pyogenic organisms were absent in fluid that was early aspirated. In consequence, then, of the mechanical factor and the toxic possibilities the symptoms must be considered as arising from two causes, first, those of a purely mechanical disturbance and, second, those from the absorption of toxicity. Owing to the limited space, sudden and massive serous effusions without the presence of pyogenic organisms may so affect the neighboring organs as to necessitate immediate evacuation, at least in part, for the relief of pressure. The changes produced by these effusions affect, first the chest wall, then the lungs, then the organs in the mediastinum, and finally the abdominal organs. Early in the streptococci form of infection the pleura presents on its surface a granular or strawberry appearance, which is not met with in the pleura where the effusion is from less virulent types of organism. In the latter the condition is often more chronic and the pleura is found to be dense, presenting the appearance of fibrous membrane.

In massive effusions the involved chest wall be-

comes distended, the sternum may be pulled over to the affected side, and the lung, if not bound by previous adhesions to the parietal pleura, is forced inward and rests against the side of the vertebra. The respiratory cycle is seriously interfered with both by reason of pressure against the lung and downward displacement of the diaphragm. The displacement and pressure on the heart is often marked and always serious and the viscera in the mediastinum—esophagus, descending aorta, the pulmonary vessels and the vena cava—are pressed down and embarrass respiration and circulation in proportion to the massiveness of the effusions.

The unaffected lung is compelled to perform the work of both though seldom itself entirely free in action. The classic picture, therefore, of marked dyspnea, cyanosis, and feeble rapid pulse is readily accounted for by the mechanical interference; the heart is overworked and death may ensue merely from change of position from the recumbent to erect or sitting posture. The depression of the displaced vena cava or the large vessels arising from the heart prevents the blood entering the heart and indirectly the brain, causing syncopal attacks. Then, too, there is difficulty in swallowing from compression of the esophagus.

While symptomatology in detail belongs to the realm of physical diagnosis, certain disturbances in the physiological performance of the anatomical structure in the thorax cause clinical signs and symptoms so definite that they must be considered equally from a surgical viewpoint. These are dullness over the affected area, displacement of the heart, absence of respiratory signs, and vocal fremitus. When there are no adhesions to prevent it, a large amount of effusion separates the lung from the chest wall. When such do exist multiple pockets and irregular compression of the lung are found. Some of these pockets may contain pure serum, others pus, and others serohemorrhagic fluid. Such complications as these offer difficulties both in diagnosis and surgical treatment. The effusions which occurred during the epidemic were usually treated before changes in the pleura could take place. These changes, such as thickening and contracture, which often pull together and diminish the circumference of the thoracic wall, are often encountered in old effusions.

The variety and characteristics of the pathological effusions that occurred during the epidemic differed only in their suddenness and massiveness and great toxicity, the *Streptococcus hemolyticus* furnishing the gravest constitutional disturbances because it produced the most sudden and overwhelming effusions. They were all, however, secondary to general streptococcal infection, influenzal pneumonia, and similar conditions, and, in a few instances, I believed them due to hemorrhagic infarcts the result of a general systemic bacteremia.

There seems to have arisen a diversity of opinions as to the best surgical treatment of pleural effusions, growing out of the findings of the various empyema commissions. At the beginning of the epidemic the effusion was so sudden and massive as to prove fatal before any operative treatment could be employed. Later on early rib resection was practised with an

*Presented before the South Branch of the Philadelphia County Medical Society, April 30, 1920.

eighty per cent. mortality; still later, delayed operation with early aspiration was practised with a further improvement in lowering the mortality, though it was still high, while further along in the course of the epidemic all operative treatment was delayed with a yet greater number of recoveries. Therefore, if one examines these findings of the commissions at the several military camps and studies the voluminous literature, he is disposed to conclude that the particular operative procedure played a less important part in the reduction of the mortality than the spent virulence of the toxic process, because, as the epidemic drew to a close, delayed thoracotomy with or without rib resection, with or without irrigation, resulted in a percentage of recoveries equal to that in civil practice and before the occurrence of the epidemic.

The report clearly suggests the wisdom of returning to the fundamental rule in the treatment of pyothorax, that is, to remove the pus as soon as its presence can be determined, for effusion is seldom, if ever, purulent early; then secure and maintain adequate drainage from the most dependent part of the abscess as long as suppuration persists. Thoracotomy with or without rib resection is the method of choice.

The addition of irrigation has not been proved valuable since a much larger number of patients so treated have been and are actually now requiring some form of collapsing operation and decortication because of the extensive adhesions that appear to have been directly caused by its use. Therefore, neither the influenza epidemic nor the empyema commission has disproved the merits of the fundamental rule that governs the operative procedure in thoracic effusion before their occurrence, viz., paracentesis, either with or without suction drainage, when serothorax is so massive as to affect by its mere mechanical presence the physiological functions of the organs in the thoracic cavity, and thoracotomy, should be performed, with or without rib resection for pyothorax as soon as its presence can be determined.

Rib resection is generally necessary when there are marked narrowing of the intercostal spaces and pleural adhesions with pockets; otherwise most uncomplicated abscesses require only intercostal incision and drainage. For the relief of pain analgesia with novocaine or ethyl chloride is usually all sufficient. Inhalation anesthesia is seldom needed and always an added danger. Not rarely during the epidemic there were instances where both a serothorax and a pyothorax became infected with mixed pyogenic organisms resulting in gangrene of the lung and osteomyelitis of the ribs. These were fatal in most cases.

When the empyema is encapsulated the x ray will best determine the most dependent point of the abscess. In all other instances the eighth or ninth interspace external to the long muscles of the back is found the favorite site. Chest and arm exercises intelligently directed are always included in the convalescent treatment in all these cases and the results are beneficial.

1222 SPRUCE STREET.

ABDOMINAL SYMPTOMS IN INFLUENZA SIMULATING AN ACUTE SURGICAL LESION.*

By THOMAS HUBBARD RUSSELL, M. D.
New Haven, Conn.

My interest in this subject was aroused by the fact that I have personally seen five cases of influenza presenting pronounced abdominal symptoms, sufficient in every case to have caused the possibility of an acute surgical lesion in the abdomen to have been entertained. The first patient diagnosed her own condition as appendicitis, on account of the severity and predominance of the abdominal pain, and came to me for an operation. Three of the patients I saw in consultation with Dr. Standish and Dr. Seabury, of New Haven, and Dr. Perrins, a naval surgeon stationed in New Haven during the war. The fifth patient I saw in the New Haven Hospital by courtesy of Dr. Blumer and Dr. Tileston, on whose service it occurred. All of these cases were in adults, and all of the patients recovered uneventfully without an operation. I hope to report the cases in greater detail at some future time. This paper does not permit of it at present.

The subject I believe to be of considerable importance at the present time on account of the seriousness of the recent epidemic, and the probability of our seeing sporadic cases for some time to come, and also on account of the frequency of abdominal symptoms, and the great difficulty so often encountered in arriving at a correct estimate of their true significance, as well as the danger of an unnecessary operation during the course of an influenza. It is now possible to formulate, on the basis of the available literature, an accurate estimate of their meaning.

We must depend principally on the literature embodied in the periodicals printed during the past two years, for two reasons. In the first place, the character of the cases encountered in the epidemic of 1888-1889 varied somewhat from those found in the recent epidemics. In the former epidemic, people of all ages having been almost equally affected, and a relatively large number having had the gastrointestinal form, characterized by nausea, vomiting, diarrhea, and hemorrhages into the intestinal tract, which have been rare in the recent epidemic. Also the acute surgical abdomen and particularly the pathology of appendicitis were not nearly as well known at that time as they are now. One does, however, find references to typhlitis in the literature of that time. Articles on influenza in the standard textbooks of today give scant or no attention whatever to the symptoms and signs frequently occurring in influenza, which would ordinarily suggest an acute surgical abdomen.

The abdominal lesion most often simulated is appendicitis, and a differential diagnosis here is made more difficult by the fact that the two conditions, at least during the recent epidemic, have occurred most frequently at the same time of life, young adults having been chiefly affected. One must, of course, always consider the possibility of a coexistence of the

*Read before the Connecticut State Medical Society, May 19, 1920.

two conditions. It would be strange indeed if they did not occasionally coexist.

Let us consider for a moment what lesions are known to occur in the abdomen secondarily to influenza. One of the most frequent is peritonitis, which may be either local or general. When local it occurs most frequently in the upper abdomen, adjacent to the diaphragm. In a large proportion of these cases it appears to be a direct extension from an adjacent empyema. When general it usually is of a fibrinous character. When purulent it is, as a rule, part of a general pyemic infection. It is not due to an extension from an infection of the appendix or gallbladder. In some cases a localized collection of serosanguinous fluid is found among the coils of intestine. The causative organism may be the *Streptococcus hemolyticus*, pneumococcus or staphylococcus. Where peritonitis is a complication, it almost always comes on during convalescence from pneumonia.

Rupture of the rectus abdominis muscle has frequently occurred during the recent epidemic, and still more frequently during the epidemic of 1888-1889. It occurs in muscles showing a Zenker's degeneration, probably due to a spasmodic contraction of the weakened muscle during coughing. It may result in a hemorrhage within the sheath of the muscle, which not infrequently becomes secondarily infected, resulting in a deep abscess. The rupture is rarely complete, and usually occurs midway between the symphysis pubis and umbilicus. One writer reports eight cases, another has seen twenty. These patients have frequently been operated upon for a supposed appendicitis.

Multiple abscesses of the kidney, and perinephritic abscesses occur infrequently.* A thrombophlebitis of the large abdominal vessels has occasionally been reported. Also a general congestion of the intestines, with submucous hemorrhages, occasionally occurs. One case of rupture of the colon has been reported.

These lesions are about the only ones at all likely to appear in the abdomen. In the great majority of cases they have come on during convalescence, or as a terminal process, and an operation would have been useless, or merely hastened the end.

There are a few who believe that there is a close relationship between appendicitis and influenza, but their statistics are not convincing. The general opinion seems to be, on the contrary, that appendicitis is a very rare complication, although a train of symptoms which would ordinarily substantiate such a diagnosis is exceedingly common. The best statistics available are from the military camps and base hospitals, as here tremendous numbers of men suffering from influenza were under observation and excellent control. Let me quote freely from a few of those which describe the frequency and the puzzling nature of the abdominal symptoms.

Camp Dix.—During the twenty-two days of the epidemic there were 6,000 cases of influenza in the hospital, and 800 deaths due to the epidemic. Synott and Clark report: "In the abdomen, meteorism occurred in some cases; in certain lethal cases it was excessive. Abdominal pain and tenderness were

present, possibly not entirely due to pleurisy, but in the light of necropsy findings to infection and hemorrhages in the rectus muscles."

Camp Logan.—A daily average of 24,000 men were in camp and 4,126 were admitted to the hospital with a diagnosis of influenza in addition to 567 with a diagnosis of pneumonia. The report states: "An interesting feature of the respiratory epidemic was the great number of patients admitted to the hospital with a diagnosis of acute appendicitis, in whom, after a few hours of observation, we changed the diagnosis to either influenza or pneumonia. About fifty cases were received whose previous diagnosis was wrongly given as appendicitis."

U. S. Naval Hospitals in Philadelphia.—Daland reports on the basis of 3,000 cases of influenza: "Reflex pleuritic pains have been erroneously diagnosed as cholecystitis or appendicitis—usually interlobar and diaphragmatic seroplastic and purulent pleurisy are not diagnosed, but the latter may be suspected when friction sounds are heard over the borders of the lung or when referred pain occurs in the upper abdominal, gallbladder or appendix regions. . . . Autopsies showed no pronounced gastrointestinal pathological change. . . . Referred pleuritic pain is often mistaken for cholecystitis or appendicitis." Billings states: "In the majority of instances there was some abdominal distension and pain on palpation, particularly in the right iliac fossa. This latter symptom cleared up rapidly, however, but during its presence markedly simulated appendicitis."

Great Lakes Naval Training Station.—McNally reports that he saw a considerable number of cases which taxed his diagnostic ability and that of his colleagues on the surgical service. He states: "The onset of acute chest conditions gave us concern in many instances. They were confused most often with acute appendicitis although we were occasionally confronted with symptoms resembling acute gallbladder disease. I have come to have a wholesome respect for the difficulties encountered in making an early diagnosis in these cases." Autopsy findings showed in some cases a moderate amount of turbid liquid in the peritoneal cavity, but the appendix and gallbladder showed no changes which could be connected with the recent condition. "To have operated upon these cases would have been a fatal mistake."

Royal Naval Hospital, Plymouth.—Smith reports: "In the earlier days patients were constantly being sent in to the surgical service with the diagnosis of perforated gastric or duodenal ulcer, less frequently as an acute appendicitis—the true diagnosis is often difficult."

Camp Dodge.—Manson reports that at one time there were a total of 8,000 cases in the hospital. The total number diagnosed as influenza from September 16 to December 15, 1918, was 10,041. He states: "In about thirty patients with pneumonia symptoms developed strongly suggestive of surgical lesions of the abdomen, which were seen in consultation with the medical service; so closely did some of these cases with chest pathology simulate appendicitis that three of the patients were transferred to the surgical wards with the diagnosis of appendicitis, but the true

condition was discovered in time, and none of them were operated upon. There were two patients with appendicitis who were operated upon, and gangrenous appendicitis was found, each patient giving a history of previous attacks of appendicitis."

University of Iowa R. O. T. C.—Rowan states that among 1,030 cases of influenza, appendicitis was not a common complication, there having been two cases. In quite a number of patients there were pain, tenderness and rigidity, localized in the right lower abdominal quadrant. He states: "This was marked enough in some cases to have led to the diagnosis of acute appendicitis and to have indicated operation in ordinary times." He felt that it was extremely important to avoid unnecessary operations in these influenza cases.

Camp Zachary Taylor.—Meyer states: "In many instances patients were sent to the surgical department, in whom the condition was diagnosed as appendicitis because of the history of abdominal pain and vomiting."

Camp Custer.—Beals and others state: "A number of patients were either admitted to the surgical wards or seen in consultation in the medical wards for pain in the right lower quadrant. Pain of a dull, aching character, referred to the right lower quadrant was the most prominent feature. . . . These abdominal signs and symptoms might ordinarily be diagnosed as appendicitis. However, it was repeatedly observed that the local abdominal signs disappeared in a short time; more rarely they persisted and increased in severity so that operation was deemed imperative. This group occurred in influenza patients, nearly all of whom later showed demonstrable signs of bronchopneumonia." Four and two tenths per cent of the cases coming to autopsy showed peritonitis, usually localized in the upper abdomen, and never secondary to any demonstrable abdominal lesion. Abdominal rigidity and tenderness of the upper abdomen were usually a reflex from pneumonia.

Camp Lewis.—Based on their experience with 7,088 cases of influenza and 1,126 cases of bronchopneumonia, Kerr and others state: "While abdominal symptoms have been rather infrequent during the course of the disease, they are, when present, the source of great annoyance. In two instances these symptoms led to operative procedures. At operation one patient was found to have a normal appendix and pneumonia developed later. The other presented an acute gangrenous appendicitis, although the leucocyte count prior to operation was 6,000. Pneumonia was not found in either case prior to operation. In another instance abdominal pain, leucocytosis and a slight jaundice suggested acute cholecystitis. Pneumonia with a resulting empyema on the right side was found and apparently produced the abdominal picture."

Camp Beauregard.—Frick reports that many patients "had vomiting; some became tender over the abdomen, imitating an intraabdominal condition."

Abrahams, Hallows and French report that in several thousand cases of influenza occurring in the British army, about 400 of which came to autopsy "Abdominal pain . . . has existed of sufficiently

severe character to lead to a provisional diagnosis of appendicitis, and even to some solicitude as to a differentiation from an acute abdominal condition urgently needing operation." Under postmortem findings, they state: "The vermiform appendix has not shown any noticeable change. We mention this because there has been a tendency elsewhere, we have been told, for certain of these influenzopneumonic patients to develop acute appendicitis."

Brooks and Gillette state that out of about 29,000 deaths in the American Expeditionary Force due to influenza only three were recorded as due to other conditions than pneumonia. Dr. Lewis Connor states on the strength of a study of reports to the surgeon general from seventy-two base hospitals scattered throughout the country: "Abdominal pain was of rare occurrence. Abdominal tenderness was sometimes encountered, but seemed usually to be either a part of a general hyperesthesia or related to inflammation in the chest which involved the diaphragmatic pleura. Very rarely it was caused by a local or general peritonitis."

Henderson and Billington, basing their statements on an experience with about 5,000 cases of influenza in a large base hospital, say: "In some cases the abdominal signs and symptoms are such as to strongly suggest an acute appendicitis, and quite a number of cases have been operated upon on this diagnosis. On the other hand, during the latter part of the epidemic, numbers of patients were sent into the hospital with a provisional diagnosis of influenza of the abdominal type, in which the condition was actually one of acute appendicitis. In one week we had three such cases in which operation was necessary. One does not regard influenza in an ordinary sense as a cause of appendicitis, but it can be readily understood that, with such a catarrhal condition of the bowel as is often met with in abdominal influenza, an acute appendix inflammation may be readily set up."

Mann, from his experience at a base hospital, states that the abdominal symptoms were frequent, might occur before other symptoms, and frequently lead to a diagnosis of appendicitis; that true appendicitis in influenza was rare, but did occasionally occur. "Acute appendicitis was so rare that we had only one case. . . . The cases simulating appendicitis gave us a great deal of anxiety."

That the abdominal symptoms are not confined to military practice, and that cases are not infrequently operated upon for a supposed abdominal lesion in civilian life is illustrated by the following abstract and quotations: Bloomfield and Harrod state from their experience at the Johns Hopkins Hospital: "In a few instances, acute abdominal pain, vomiting, or diarrhea, ushered in the disease."

William R. Williams states: "Another group of cases showed chiefly abdominal symptoms. . . . One such patient was admitted to the New York Hospital with fever and a good history of acute appendicitis. The abdomen was rigid and sensitive in the region of the appendix. Because she had a little cough and influenza was so prevalent at the time, operation was delayed for a little time. Later there developed a double bronchopneumonia, and the patient recovered

without surgical treatment. There were other patients who had both an operation and pneumonia to get over. . . . Another patient was operated upon for acute cholecystitis. The gallbladder was normal and later pneumonia developed."

Dubs operated upon two patients with supposedly ruptured appendix during influenza. In both cases no surgical condition was found, and no real lesion of the appendix, but a slight congestion of this region. In other cases he states that individuals have lain in the hospital for twenty-four hours with a diagnosis of abdominal grippe, and the patients were then operated upon and a ruptured appendix located.

Manges states: "Another symptom referable to the abdomen is pain. At times this may be so severe that acute abdominal conditions may be suspected. In the case of a child recently admitted to the Mt. Sinai Hospital, the abdominal pain was so severe and cramplike and the rigidity of the abdomen was so great, that in the presence of fever, and the absence of other symptoms and signs, a diagnosis of acute appendicitis was made. As nothing was found at the operation, the true diagnosis of influenza became apparent. I have seen a number of patients in my own service in whom the main symptom was intense abdominal pain, which was especially referred to the epigastrium."

Delbet has described two patients in his private practice in whom there were all the symptoms ordinarily found in an appendicitis with abscess formation, including a palpable mass. The first was operated upon and died, the appendix having been found normal, but there having been a collection of serosanguinous fluid between the loops of intestines. In the second case, profiting by his experience in the first, he did not operate, but used medical treatment, especially antistreptococcic serum, with rapid improvement and restoration to health. In both of these cases the abdominal symptoms developed during convalescence from influenza. He is firmly convinced that these patients should be treated medically, and that it is poor judgment to operate. He makes the suggestion that the streptococci are carried through the intestinal wall by the lymphatics of Peyer's patches. He states that one must be on the lookout for these cases during convalescence from the grippe.

Reissman states: "Pain and tenderness in the right iliac fossa suggesting appendicitis were noted in several instances, but in my personal experience none of these cases were appendicitis; virtually all were examples of pain referred from the chest."

Villard has reported four cases of influenza closely simulating appendicitis, two of which were referred for an operation. All recovered within a few days without operation. He states that the most important part of the treatment is to abstain from operation, which is very dangerous, and treat the patient with an ice cap and enemas.

From a thorough examination of the literature, at least since the recent epidemic, and from my own limited experience there is, I believe, sufficient evidence to warrant the statement that the complication of surgical appendicitis or cholecystitis or any other

surgical lesion within the abdomen requiring operation is very infrequent, but that abdominal pain and tenderness are extremely frequent, and are in the majority of cases either reflex, when present in the upper abdomen being due to irritation in the course of the 9th and 10th intercostal nerves, and when present in the lower abdomen to irritation of the 11th and 12th intercostals or due to a more or less general congestion of the intestines. Less frequently there is a collection of serosanguinous fluid in the abdomen; in these cases the condition of the patient is not benefited by operation, but rather harmed. This fluid will be absorbed in time if the patient survives. Occasionally there is a purulent local or general peritonitis, most often present in the upper abdomen, which is generally a terminal picture of a general pyemia, or the extension through the diaphragm of an empyema. One must always bear in mind the frequency of a hemorrhage or abscess within the rectus muscle, which has often been mistaken for a ruptured appendix. In these latter cases simple evacuation under local anesthesia is sufficient to affect a rapid cure.

One should be especially cautious in making a diagnosis of acute appendicitis or gallbladder disease during or immediately following influenza. During the course of an epidemic, it should always be borne in mind that there is a possibility of the abdominal symptoms being the first to appear. If the patient has other symptoms of, or is convalescing from influenza or influenzal pneumonia, one should be extremely conservative in recommending an operation for appendicitis or gallbladder disease. It is certain that a large number of unnecessary operations were performed during the recent epidemic.

The following points should be remembered in making a diagnosis of appendicitis in these cases:

In uncomplicated influenza, there is almost always a leucopenia. In surgical appendicitis complicating influenza there is usually a considerable leucocytosis. A leucocytosis of over 20,000 in the first eight hours or so of an appendicitis is rare, and would be strongly suggestive of pneumonia. It is possible to have an appendicitis without any increase in the leucocytes.

In chest conditions, the pain is most often referred to the upper abdomen, and in most cases is rather more diffuse than in appendicitis or cholecystitis. In chest conditions, also, the facial expression does not indicate that the patient is suffering as acutely as would be the case if a real surgical condition were present in the abdomen, but is resigned or lethargic. The rigidity of the recti is more likely to be equal, where the condition is due to a chest lesion, and light, superficial palpation is apt to cause the patient almost as much pain as deep palpation, which is not usually true where a real surgical condition is present within the abdomen.

A movement of the alæ nasæ with respiration is very suggestive of a chest lesion, usually being absent in surgical lesions of the abdomen, unless extremely advanced. Cyanosis and rapid breathing are suggestive of a chest lesion. Jaundice and vomiting occur so frequently in influenzal conditions that their presence should not be construed as indicating a surgical lesion.

In concluding, I want to emphasize the following points:

1. Influenza is a protean disease.
2. Abdominal symptoms which would ordinarily indicate the need of an urgent surgical operation are commonly present during influenza, and their frequency is not sufficiently brought out in the text-books.
3. Conditions requiring an abdominal operation during influenza or its convalescence are exceedingly rare.
4. While in some cases, a differential diagnosis is extremely difficult, the safest procedure in doubtful cases is to adopt an expectant treatment.
5. In case an exploratory operation is decided upon, a local anesthetic is advisable.
6. A surgical abdominal lesion and influenza may occasionally coexist.
7. Many unnecessary and harmful operations have been performed during the course of influenza, due to the lack of appreciation of the frequency with which abdominal symptoms occur in influenza.
8. The great majority of cases showing abdominal symptoms have no surgical basis, but are either reflex, or due to some condition which would not be benefited, but rather harmed by a laparotomy.
9. The chest should always be carefully examined before operating for a supposed acute surgical lesion of the abdomen.

THE TREATMENT OF DRUG ADDICTION.

By THOMAS F. JOYCE, M. D.,

New York,

Resident Physician in Charge, Riverside Hospital,
North Brother Island

Drug addicts may be divided into two general classes. The first class is composed of people who have become addicted to the use of drugs through illness, associated probably with an underlying neurotic temperament. The second class, which is overwhelmingly in the majority, is at the present time giving municipal authorities the greatest concern. These people are largely from the underworld or channels leading directly to it. They have become addicted to the use of narcotic drugs largely through association with habitués and they find in the drug a panacea for the physical and mental ills that are the result of the lives they are leading. Late hours,

dance halls, and unwholesome cabarets do much to bring about this condition of body and mind and in a great many cases these people are found far below the standard mentally.

On August 25th last a hospital for the treatment of drug addiction was opened at Riverside Hospital on North Brother Island. While a few isolated cases had been treated there previously, up to that time it was found practically impossible to give cases withdrawal treatment in large numbers. Beginning September 1st an organization was established whereby we were enabled to treat successfully one hundred cases a week when required.

When a drug addict reached the hospital his pedigree was taken and he was admitted to the receiving ward, where all his clothing and belongings were checked up and an entire new outfit given him, including hospital shoes. From this building he was taken to what we term the preparatory ward, where after a period of six days he was brought down to the lowest amount of narcotic that would hold him without the usual signs of drug deprivation. Our experience has taught us the absolute uselessness of ascertaining the amount of daily consumption before treatment. For the majority of cases the amount is very much increased for fear of a too sudden reduction.

We have been taught that in the vast majority of cases they are using much larger amounts than is necessary for their bodily comfort, in other words, most of our patients have come to the hospital not only feeling comfortable but actually intoxicated from excessive doses of the drug. We have been taught that after two or three days in the hospital the oldest offender can be made reasonably comfortable on from two to three grains in twenty-four hours, notwithstanding the fact that most of them have told us that they were consuming from twenty to sixty grains of morphine or heroine in twenty-four hours. Four fifths of the 2,300 patients treated at Riverside Hospital were addicted to heroine while about one-fifth were addicted to morphine, opium pipe smoking, laudanum, or paregoric. About twelve and one-half per cent. of the heroine addicts were continual users of cocaine while five per cent. would be termed occasional indulgers. The fact of the addiction being complicated by the use of cocaine made little or no difference with us during the period of preparation, they just simply did not get it and did without it. The use of cocaine itself gives none of the symptoms of deprivation as do the products of opium. During this period of six days reduction we gave them a full amount of catharsis but there was no drastic purgation. We employed a system of gastrointestinal elimination on the fourth day by giving capsules of calomel, ipecac, rhubarb, atropine and strychnine, supplemented by a series of colonic saline irrigations. The free catharsis that this treatment caused was usually quite effectual and on the fifth day elimination by this method was discontinued, to be resumed again on the sixth day.

At six o'clock on the morning of the seventh day the patients are given a large dose of castor oil followed shortly afterwards by a small dose of morphine, the last they receive in the institution

unless otherwise indicated. About four hours later the first signs of drug deprivation are usually experienced. This is a signal to start using a therapeutic anesthetic. At Riverside Hospital we use the hyoscine hydrobromate. I may say here that we use hyoscine internally practically with the same object in view that the general anesthetist employs ether, in other words, as these various symptoms reappear, small but adequate doses of hyoscine are given at irregular intervals, depending upon the physiological action in the particular case. Personally I find hyoscine, when used with reasonable care and in small doses, and particularly after thorough and satisfactory elimination, a perfectly safe therapeutic agent, wonderfully adapted to this stage of the treatment. During this period, which we have termed the period of therapeutic anesthesia, we are combating all the phenomena attending narcotic deprivation, such as vomiting, general restlessness, intestinal colic, cramps in the legs, and a rapid, feeble pulse. These characteristic symptoms are held in check by the frequent administration of small doses of hyoscine, usually hypodermically. At the end of thirty-six hours, under favorable conditions the hyoscine is discontinued and we arrive at the period of convalescence. Before considering this period it might be well to mention some of the difficulties encountered in connection with the hyoscine period. During the period of hyoscine administration no food whatever is given but plenty of alkaline waters.

In the first place, no two cases ever present the same symptoms at the same time, consequently every case presents an individual problem. In one case it may require only nine or ten doses of 1/300 of a grain to keep the patient comfortable, while in another case thirteen or fourteen doses of 1/250 of a grain may be required to combat the symptoms of deprivation. Again, the patient may have been a habitual cocaine user and we find this type gives considerable trouble during the withdrawal treatment; they very frequently after eighteen to twenty-four hours of hyoscine anesthesia become maniacal and often go into convulsions. We have found that a single dose of morphine at this stage will counteract these symptoms and in no way interfere with the hyoscine treatment, which is resumed two or three hours later. At this stage of the treatment we produce what might be properly termed a modified twilight sleep. After thirty-six to forty-eight hours of withdrawal treatment the patients are found to be moderately intoxicated by the accumulative action of hyoscine; even after a period of twelve hours they experience all the customary signs of their intoxication and we describe this period as the posthyoscine hysteria. This is followed in twelve hours by a general feeling of depression and weakness which lasts from two to seven days, depending upon the recuperative powers of the individual and the duration of the addiction. During this early convalescent period they are given hot baths and mild hypnotics, if indicated, and a restricted diet.

Forty-eight hours after the last dose of hyoscine is given the majority of patients are ready to be transferred to a building which we term the first convalescent ward. When patients are not quite

ready to be sent to the ward, they are transferred to a building known as the infirmary, for the reception of patients whom we term laggards. These laggards comprise patients who through long years of addiction and numerous treatments have become de-vitalized and their convalescence is usually prolonged and tedious. After a week or ten days in the first convalescent ward the patients are transferred to the final convalescent ward, where their physical reconstruction begins. They are given light exercise in the gymnasium and they are taught the useful lessons of clean living. After a week of walking around and indulging in light exercise they are assigned to some work which we have included in our program under the name of occupational therapy. The application of this treatment is, I might say, the most trying in the entire course, for the average drug addict of this type is lazy, to say the least, but we have been able at Riverside Hospital to prove to them the necessity for their physical upbuilding, if they are to abstain from drug addiction. For after all we can bring them to a state of physical balance where the future use of the narcotic drug is unnecessary to their physical needs; we can keep them long enough to show them the folly of their addiction, we can impress upon them the fact that they do not need the temporary mental exhilaration that goes with its use, but as yet we have found nothing that will remove the psychic trauma that its prolonged use has inflicted.

The prognosis in drug addiction, to my mind, is one of the most difficult in the entire field of medicine, and in venturing upon one we must take into consideration the etiological factors that led to the addiction, the type of the individual, the environment to which the patient will return, and the encouragement that society in general will mete out to this unfortunate sufferer upon his discharge from our institution.

A NEW METHOD FOR DETECTING DRUG HABITUÉS.

BY HAROLD C. LANE, M. D.,
Denver, Colo.

The finger of a suspected opiophagic patient is stabbed with an automatic lance. The blood is drawn into a Gowers's blood pipet holding two cm. This is expelled into a small test tube five by five-eighths cm., containing one c.c. of normal saline solution. This is repeated for five more saline tubes. The tubes are numbered 1-2-3-4-5-6. Shake each tube gently immediately after the blood is introduced. Prepare two more saline tubes and number them 7 and 8. If any shreds or clots of blood should be present, remove them with a sterile platinum wire. As a rule they will not be present.

Tubes 1 and 2 are controls, containing only saline solution and blood. To tubes 3 and 4 add .2 c.c. of a 1-100 solution of morphine sulphate in distilled water. The solution should be neutral, it must not be either acid or alkaline therefore it should be tested with red and blue litmus paper and with phenolphthalein and methyl orange indicators. To tubes 5 and 6 add .2 c.c. of a 1-200 solution of morphine sul-

phate made with a good grade of the drug in distilled water. Tubes 7 and 8 contain the blood of normal individuals.

RESULT OF TEST.

After standing at room temperature out of the light for from twelve to twenty-four hours or even less, tubes 1 and 2 (controls) show complete inhibition of hemolysis with a clear supernatant fluid. Tubes 3 and 4 show almost complete inhibition of hemolysis with a very cloudy supernatant fluid. This flocculent flaky appearance is the positive test for a drug habitué. Tubes 5 and 6 show a modified flocculent appearance of supernatant fluid. Tubes 7 and 8 (true controls of normal blood) show a clear supernatant fluid with complete inhibition of hemolysis. I would like to caution the investigator that upon agitation of the tubes, the flocculent deposits settle to the bottom of the tubes. The tubes should be placed against a black background in order to accurately interpret the results, as a clear bright light obscures the readings.

It is also possible that the reaction takes place with any of the narcotic drugs such as heroine, codeine, and others. The blood of a drug user has amboceptor with at least one narcophore binding cell which has an affinity for the drug the patient is taking. This is a rapid method of testing the blood of a drug addict as the blood does not have to be passed through the lower animals to secure antiserum. All the glassware should be sterile, the technic is simple and anyone can do the test. The test may also be done with rabbit serum which has been sensitized with the blood serum of a drug habitué. I do not state that this test is perfect but in the course of time it should be made an aid to diagnosis.

A BACTERIOLOGICAL STUDY OF RIPE OLIVES.

BY RANDLE C. ROSENBERGER, M. D.,
Philadelphia,

Professor of Hygiene and Bacteriology, Jefferson Medical College.

This study of ripe olives was made under the auspices of the Dairy and Food Commission of the State of Pennsylvania following several epidemics of botulism (attributed to ripe olives) with fatal results in different parts of the United States. In all, there were more than two hundred and fifty samples examined, including loose olives, canned varieties, and a large number in bottles. Combinations of ripe olives with pimento (sandwichola) were also included.

All specimens of olives examined were in perfect condition regarding canning, that is, there were no swelled cans, none buckled or leaky, and those in jars and bottles presented no leaks whatsoever. Some of the cans, however, were dirty and shopworn. There were never any offensive odors of putrefaction or decomposition, and in the majority of samples, the flavor was good, though in a few an insipid taste was noted. The consistency of the fruit was extremely variable, as was the color, which varied from yellowish green to dark green and to a reddish purple, and a number of cans contained olives of variegated colors.

When placed in a mortar and crushed with a pestle, some were so ripe or intensively treated chemically that the pulp was immediately reduced to a paste, the pit being expressed at once. In others a great deal of pressure was needed even to crush the pulp and the pit was never cleanly removed. Taking the olive between the fingers and thumb, pressing in the longitudinal axis and exerting but gentle pressure, was all that was necessary to make the pit fly out in some specimens and crush the pulp. In twenty-two specimens this pasty condition was noted. In other lots of fruit no amount of pressure between the fingers and thumb could crush the olive or expel the pit.

Thus it can be seen that even in the same cans, olives exhibiting several degrees of ripeness or various stages of chemical treatment were present, especially in the small variety. In three instances an actual blemish was seen upon the fruit; in these specimens almost every olive in the can was marked with small white specks, about the size of a pin head, resembling an insect bite. Removing several of these small spots, there were observed, upon microscopical examination, numerous bacteria, resembling in morphology and staining characteristics *Bacillus proteus*. When these olives were squeezed a jet of fluid squirted from the little specks.

In two specimens, Grecian ripe olives, the fruit was of a reddish purple color, showed longitudinal fissures (cuts), and while the pulp was extremely soft, the pit was adherent. The olives that were collected in bulk, when allowed to stand in the bottles for a day or two after examination, soon became covered with mold fungi. When first received they were moist, showing that they had been covered with liquor when offered for sale. One or two samples presented fruit with part of the skin peeling off, and these were distinctly sour to the taste. The technic employed in the bacteriological examination of these olives was as follows:

After numbering the specimens, the top of the can or jar was cleaned with a rag, and then exposed to the flame of a bunsen burner, or placed in boiling water, to remove any bacteria from the surface of the receptacle. The can or jar was next opened with a can opener, which was always kept in a bath of boiling water. Upon opening the can, the first several layers were removed with a sterile forceps, and from the depths of the can at least four large or six small olives were placed in a sterile mortar and then cut with a sterile scissors or crushed with a sterile pestle. After crushing the pulp, about thirty c. c. of sterile salt solution was added, and the pulp thoroughly ground in this solution. Then with a long sterile needle (made expressly for anaerobic cultures) at least one to two c. c. of suspension were drawn into a sterile ten c. c. syringe and injected into deep tubes of culture media, the surface of the medium covered with sterile oil and the tubes kept at ordinary room temperature. The culture media used were alkaline litmus glucose agar, alkaline gelatin and a medium made with pumpkin as a basis, solidified with agar. These inoculations were kept under observation for at least two or three weeks. No evidence of growth

or liquefaction occurred up to this time. Sterile bouillon was also inoculated, using ten c. c. of the liquor from the cans or jars. In almost every instance, at body temperature (37° C.) in an aerobic atmosphere, a firm pellicle developed within twenty-four to thirty-six hours. These inoculations were made into bouillon to determine if the liquor contained living aerobic organisms.

Regarding the investigation of the toxicity of the olives, the salt solution suspension made of the pulp was injected intraperitoneally into guineapigs and white mice. One c. c. was injected into the white mice and two c. c. into the guineapigs. (In the white mice the dose injected was about one twentieth of the body weight of the animal.) It is asserted by Von Ermengem and others that .0005 c. c. of toxin is fatal to guineapigs and mice, so these animals surely would have received an amount sufficient for poisoning, if present in samples. These animals were kept under observation for a number of days.

In another set of animals, feeding experiments were conducted upon white mice. The salt suspensions of the olives were placed upon bread and this was all the animals were given for twenty-four hours. It is said that the most pronounced symptom of botulism in the lower animals is paralysis of the posterior extremities. No animal under observation presented these symptoms.

Three mice (3883, 3865, 1263) died of traumatic peritonitis following inoculation (six hours, twelve hours, twenty-four hours); one mouse (6675) was killed as a result of a fight; two others died (3865, 1264) from inoculation, but no lesions were observed at autopsy, and the heart blood was free from bacteria. One mouse died within twenty-four hours after being fed on soaked bread. No lesions were demonstrable at autopsy, and its blood was sterile. One guineapig (3862) died after four days, but autopsy showed few adhesions in peritoneal cavity and the blood was sterile.

As none of the animals died of botulism it was thought that by allowing the suspension to stand for a day or two in the ice box more toxin (if present) would be brought into solution. But even after standing this length of time, and inoculating and feeding mice and guineapigs, no ill results were noticed. In examining the sediment of the salt suspension, organisms of some sort were observed in all specimens. A number contained hyphæ and spores of mold fungi; quite a number contained yeasts and molds, while the greatest number showed gram negative bacilli. A few others showed gram positive bacilli. Some contained gram positive micrococci, arranged in short chains, and in a few the chains of micrococci were gram negative. In two specimens a bacillus was encountered which possessed the characteristics of the *Bacillus tetani*, i. e., about the same size and with a terminal round spore. It was generally gram negative, however. Long filaments resembling leptothrices, and bacilli corresponding in morphology to lactic acid bacilli were also encountered. In some specimens, even though the consistency of the fruit was pasty, very few organisms were found, and in others, every field of the slide was well filled with microorganisms.

If the ripe olives would cause botulism, there was abundant opportunity for the production of the disease, as there were three of us working upon the specimens, each eating at least twelve to twenty olives a morning, during examinations lasting several weeks. On one occasion, several people ate at least one quart of the olives in the course of two hours and no untoward symptoms resulted.

To determine whether the fruit would undergo any putrefactive changes after being kept for a certain time, a number of olives were placed in sterile bottles and placed in various parts of the laboratory. Some had a small quantity of the original liquor upon them while others were kept without liquor. Some were kept at ordinary room temperature upon the window sill of the laboratory, some in a dark closet, while others were kept in the refrigerator. One can was kept half full of olives with some of the original liquor upon them. (The ordinary room temperature during these observations varied from 18° to 21° C.). At the end of four months no disagreeable odor was noticeable and except in those where no liquor was left on specimens, slight shrinkage of the fruit was observed, otherwise there was no change in the appearance or consistency. In all specimens, however, a mold fungus developed.

In one bottle, holding 500 c. c., olives of various brands were placed with liquor completely covering the fruit, and on the surface of the liquor a pellicle of mold fungus developed and one or two olives on the surface were found quite soft and mushy, but the majority of the fruit was as good as when placed in the jar. In all specimens where the mold odor was not predominant, the agreeable aromatic odor of the ripe fruit was noticeable. In the can which was kept unsealed on the window sill for four months a rather tough mold pellicle developed but the fruit for the most part was intact and absolutely odorless. In a sterile flask holding the liquor of several containers which stood around the laboratory for over three months, complete evaporation of the liquor occurred and the residue gave off an oily odor but lacked anything of a disagreeable nature.

Four months after date of preliminary examinations, specimens that were kept upon the window sill and working table, exposed to daylight, and those from inside a dark closet, were ground up in a sterile mortar and sterile salt solution added. This salt suspension was inoculated into guineapigs in amounts of 0.5 c.c. subcutaneously. None of the animals exhibited the slightest ill effects, showing an entire absence of the development of any poisonous substances in olives that were originally sound and which had been left standing at ordinary room temperature for a period of several months (under various conditions of sunlight). All the olives examined, as stated before, gave off a pleasant, aromatic odor, and even when kept for a long period of time (four months) with and without the preserving liquor, the same aroma was noticeable and in some an oily odor was observed.

Tubes containing sterilized macerated ripe olives were inoculated with a strain of *Bacillus botulinus*

obtained from the Department of Agriculture in Washington, and though no difference in the consistency of the olives was noted, yet a disagreeable, rancid, heavy penetrating odor developed anaerobically which persisted for a number of days following the removal of the oil making the anaerobic seal. Regarding the strength of the liquor upon these olives as originally prepared, it was found by LaWall that "the density of the brine of the moist packed olives was investigated and found to vary greatly. The lowest figure was 1.75 per cent. of salt present and the highest was 9.3 per cent., the average being slightly less than four per cent." In the unripe olive the salt content of the liquor is usually about six to seven per cent. With reference to the preparation of the olives in glass, it has been found that the temperature to which these packages are exposed in preparation was far lower than that where the olives were packed in cans. In those instances where deaths occurred from botulism it was stated that the fruit gave off an offensive, putrid odor.

In my opinion ripe olives when packed should be sound and placed in a six or seven per cent. solution of salt and sterilized as thoroughly as any other canned fruit or vegetable. Where glass packages are used, naturally the glass must be of a suitably tempered nature to withstand heating to a high degree; the commercial glass used will not stand this high temperature without cracking.

It is probable that the olives which caused the death of individuals partaking thereof were unclean, putrid or decomposing when packed, and the heat to which they were exposed was not high enough nor prolonged sufficiently to destroy the toxins or spores already developed. Dickinson (1) and his coworkers proved that the spores of the *Bacillus botulinus* resist the temperature of boiling water for two hours, and a temperature of 95°C. for more than three hours. According to earlier observers, especially Von Ermengem, a temperature of 80°C. for one hour effectively destroyed the spores of the organism. The work of Burke (2) demonstrates the ubiquity of the *Bacillus botulinus*. She found in five localities in Central California fifty or more miles distant from each other, *Bacillus botulinus* in bruised and bird pecked cherries, crop, gizzard, and intestinal contents of birds, hay, leaves, insects, spiders, bush beans, etc. She concludes that the *Bacillus botulinus* is widely distributed in nature, and that it is present in the garden and on fruit and vegetables when they are picked and not necessarily associated with active decay. The observations of Cheyney (3) proved that an average of eight per cent. of canned foods examined contained living organisms, and that the usual methods of processing are inefficient in that they do not result in a complete sterilization.

What is desirable is a sterile product, whether this product be meat, olives, or vegetables of any kind, and until this end is attained, there will occur outbreaks of food poisoning of one type or another with perhaps some fatal results. The work of Weinzirl (4) upon canned foods is also instructive in demonstrating the care exercised by commercial

industries in the canning of many foodstuffs.

From the examinations made of various brands and varieties of ripe olives, no evidence of *Bacillus botulinus* or its toxin was found. Bacteria were present in all preparations but no anaerobic organisms developed in the gelatin or litmus lactose agar or pumpkin agar (which were made alkaline in reaction).

From the rancid, offensive odor developed in the macerated olives by the growth of *Bacillus botulinus* intentionally added, it would appear that where any canned foodstuff gave off this odor it should immediately be rejected. The number and variety of organisms found in spreads demonstrate that gross carelessness was exercised in a sanitary sense in preparation of the fruit, or that these bacteria probably represent the organisms found in overripe or decaying fruit.

LONDON LETTER.

Smoke Evils in London.—Disabled Ex-Service Men.
(From our own correspondent)

LONDON, June 23, 1920.

On June 18th the Ministry of Health issued an interim report of the Department Committee of Smoke and Noxious Vapors Abatement, in which it is stated that means which produce little or no smoke are available and practicable for cooking, heating water, and warming rooms, and among reasons for issuing an interim report is that the great housing schemes now being undertaken with the aid of the Government subsidy afford a unique opportunity for securing these means in the new houses. The committee profess themselves as satisfied that domestic smoke from the burning of raw soft coal is not only a serious menace to health and a damage to property, but also wasteful, as all the valuable byproducts are lost. Central hot water installation is strongly advocated, from the standpoint of health, comfort, and economy. Among the conclusions and recommendations made by the committee are the following: Whenever a supply of gas is available a gas stove shall be installed instead of a coal range.

The cheapest and most efficient way of providing hot water, where a central supply is not practicable, is by a coke-fired boiler. As far as practicable gas fires, hot water radiators, or electric radiators should entirely supersede the old fashioned open coal fire, adequate means for ventilation being provided. In none of the houses built with the assistance of the Government subsidy should more than one or, in exceptional circumstances, two coal grates be installed. Whenever coal ranges and coal grates are installed they should be of a type adapted to the use of coke as well as of coal.

Adequate means for regulating the draught should in all cases be provided. The central housing authority should decline to sanction any housing scheme submitted by a local authority or public utility society unless special provision is made in the plans for the adoption of smokeless methods for supplying the required heat. The only exception to this should be when the central authority is fully satisfied that the adoption of such methods is impracticable. The Government should encourage the coordination and extension of research into domestic heating generally.

* * *

On June 16th evidence was given before the House of Commons Select Committee on Pensions with regard to the employment of exservice men, and particularly disabled men. Mr. T. W. Phillips, principal assistant secretary to the Ministry of Labor, who has charge of the employment department, stated that there were 420 employment exchanges and 1,196 branch employment offices in the United Kingdom. In the period since the armistice to May last the exchanges had found employment for 1,612,000 individuals, 824,000 men and 490,000 women, of whom about 403,000 were exservice men who were placed in employment for the first time since leaving the forces. In addition, there were large numbers of exservice men whose return to preservice employment was arranged by the exchange under the demobilization scheme period. During the same period about £988,200 was paid out in unemployment benefit under the national insurance acts, and about £52,534,000 in out of work donations.

In August, 1918, there was established at Catherine Street, Aldwych, a special exchange to deal with disabled men only, the staff itself consisting almost entirely of disabled men. A member of the exchange staff attended the office of the Neurological Board at Lancaster Gate and took particulars of the neurasthenic men. About 1,700 cases had been registered and thirty-three placed monthly, while 337 had been submitted for training. These cases presented exceptional difficulty, as most employers declined to take neurasthenic men. The manager was submitting a scheme for coordinating curative treatment and placing. On June 4th last, the number of firms on the national roll was 16,989, employing an aggregate of 2,496,677 work people, of whom 140,759 were disabled. The total number of disabled men placed in employment through the exchanges since the armistice up to May 28, 1919, was 71,983.

An analysis which was compiled of the types of disability of the disabled men who had applied to the exchanges for assistance in obtaining employment from June 17, 1918, to the end of May, 1920, showed: Injuries to arms, 40,569 men; injuries to legs, 42,610 men; lung affections, 16,967; heart affections, 16,581; neurasthenia, 12,406; internal injuries, 14,090; rheumatism, 10,009; debility and weakness, 8,040; injuries to head, 7,801; injuries to eyes, 6,811; muscular ailments, 4,407; epilepsy, 2,099; mental derangements, 1,425; deafness, 3,127; various minor ailments, 25,881.

Remittances should be made by New York Exchange, post office or express money order, payable to A. R. Elliott Publishing Co., or by registered mail, as the publishers are not responsible for money sent by unregistered mail.

Entered at the Post Office at New York and admitted for transportation through the mail as second class matter.

NEW YORK, SATURDAY, AUGUST 14, 1920.

AUTHOR PHYSICIANS—DR. CONAN DOYLE.

Although Sir Arthur Conan Doyle, the creator of Sherlock Holmes, was for several years a practicing physician, it was foreordained from the very beginning of his career that literature rather than medicine should be his life work. He began writing stories of adventure, his biographers tell us, at the feeble old age of six. Against such precocity what chance was there for mere medicine? Altogether Dr. Doyle's medical activities covered a period of about ten years, not counting the time he spent in South Africa during the Boer War, when he was honorary senior physician and registrar in the Langman Field Hospital.

Dr. Doyle was born in Edinburgh on May 22, 1859, and was graduated from Edinburgh University in 1881 as an M. D. A year later, after a voyage to South Africa, he began practicing in Southsea, but the practice of medicine to him was more of a makeshift than anything else, despite the elaborate preparation he had made for it at Edinburgh and in Germany. All through his student days he devoted his leisure hours to writing, and in one of the professors at Edinburgh, Dr. Joseph Bell, a man of astonishing analytical and deductive powers, he found the original from whom Sherlock Holmes was subsequently drawn.

It was in 1878 that his first story was published in *Chambers' Journal*—a romance based on an old Kaffir superstition, but it was not until nine years

later, when he was attending patients in Southsea, that his *Study in Scarlet* came out. It was in this volume that Sherlock Holmes and Dr. Watson made their first appearance, but the popularity of the book was not astonishingly great nor the royalties from it large. Dr. Doyle continued the practice of medicine. In 1890 his *The White Company* and *The Firm of Girdlestone* were published, and he left Southsea and went to London as an eye specialist. Soon thereafter the royalties from his books and the checks for his serials and short stories began to pour in, and he forsook the medical profession forever.

What the loss to the medical profession may have been is uncertain, but there is no doubt that the gain to literature was considerable. As a writer Dr. Doyle has firmly established himself in English literature. Few writers have been more versatile than he. We think of him mainly in connection with the Sherlock Holmes stories. Probably on these his greatest fame will rest, though critics contend that from a literary standpoint his best work was done in the field of the historical novel—*The White Company*, *Micah Clark*, *The Refugees* and others, tales of olden times full of action and hairbreath escapes, good description, convincing atmosphere, and painstaking fidelity to detail.

Dr. Doyle is also a poet and historian. Two volumes of poems—*Songs of Action* and *Songs of the Road*—stand to his credit, and in the field of history he gave us two volumes on the Boer War and was Britain's official historian of the British campaigns in France and Flanders during the world war. The British Government gave him sole access to official records and other sources, from which he compiled the six volumes which tell of the British army's part in the struggle against Germany.

As if this were not versatility enough, Dr. Doyle also has won laurels in the playwriting field. Perhaps the best known of his work in this line is *Waterloo*, a one act play written in 1894, in which Sir Henry Irving played the leading part, both in this country and in London.

However, it was Sherlock Holmes who gave Dr. Doyle his tremendous popularity, a popularity that has had few parallels in literature. With these stories of crime detecting he set a vogue which brought out a host of imitators. As for detective stories today on the Holmes model, their name is legion. This is not to say that Dr. Doyle was the

first to write a detective story. The controversy over whether he or Edgar Allan Poe created the detective story is a literary *cause celebre* which has raged for many years. Certainly Poe wrote the first detective stories, but just as certainly Dr. Doyle created the modern detective as he exists in the literature of our time.

In all Dr. Doyle's stories there is a masculine, healthful and courageous spirit. His pages are stimulating from first to last. He sees life as a whole, and his outlook is broad and genial. His is a sane philosophy of life, and one does not have to be a good guesser to size him up for a man of action, an outdoor man, a devotee of all outdoor sports, who has been whaling in the Arctic seas, has made balloon and airplane flights, has been skiing in the Swiss Alps, and is a crack rifle shot and an inveterate golfer. Time was when he was a formidable foe at football and cricket, but advancing years have crowded those activities into the background.

In recent years Dr. Doyle has become greatly interested in the occult science, and is one of the staunchest upholders of the theory of spiritism. In all Dr. Doyle's writings only one volume is of a medical nature and that in no wise technical—*Round the Red Lamp, Being Facts and Fancies of Medical Life*, published in 1895. Dr. Doyle was knighted in 1902.

EARLY SYMPTOMS OF NERVOUS DISEASE.

The trend of medicine seems to be in the direction of preventive treatment. Sir James Mackenzie, the great specialist, has retired while at the height of his fame to the small city of St. Andrews in Scotland to endeavor to carry out his views with regard to the early symptoms of disease. His idea is to teach the general practitioner how to recognize and treat the early symptoms of disease, for the general practitioner is the only man who is likely to have the opportunity of observing early symptoms. This is the essence of preventive medicine. This seemingly most rational conception of the practice of medicine has caught the imagination of the British medical profession; at the meeting of the British Medical Association the subject was referred to at every turn, and in the papers read the necessity for early diagnosis was dwelt upon. If a disease can be diagnosed before it has gained a foothold, proper treatment, though not necessarily always therapeutic, will generally prevent it from progressing. Perhaps cancer is the most selfevident example of this truth. If cancer can be diagnosed at an early

stage, treatment can be applied which promises most satisfactory results. As with cancer so with most other diseases early diagnosis ensures successful treatment.

Dr. Henry Head at the recent meeting of the British Medical Association opened a discussion in the section of neurology and psychiatry by reading a paper dealing with the early signs and symptoms of nervous disease and their interpretation. He pointed out that the experience and outlook of the family physician leads him of necessity to a different attitude toward early signs and symptoms than that of the specialist. The former sees so many apparently serious conditions pass away that he tends to become sceptical with regard to the minor manifestations which often lead to permanent disability. On the other hand, the knowledge of the consultant leads him confidently to anticipate the worst. Moreover, early symptoms frequently produce so little discomfort that a medical man is not consulted. Nearly all histories of illness taken from the laboring population start from the moment when the patient was forced to leave his work. Among the well to do, the story usually begins with the first visit of the doctor. Such symptoms as precipitate inactivation or slight changes in articulation, though trivial manifestations, may be of profound diagnostic importance. Again, early signs are not only neglected because they seem trivial, but the physician frequently omits to establish their true nature during the short period of their existence. Frequently the significance of some symptom or sign is not appreciated owing to the adoption of a misleading general diagnosis. The early pains of spinal syphilis are thought to be due to fibrositis. Disseminated sclerosis frequently begins with short attacks of what is called influenza, the temperature is raised little if any, but the patient feels ill, with a general sense of powerlessness. This may be accompanied by transitory loss of vision, diplopia, or incontinence of urine. But the diagnosis of influenza has blinded the physician to the condition with which he has to deal. Sometimes the history though accurate in every particular may be almost perversely misleading. A cervical rib is a congenital abnormality and yet the symptoms and signs it produces may become manifest for the first time at almost any age.

The war has taught us much concerning both functional and organic nervous disease and perhaps especially concerning the different varieties of headache. The question of headache alone provides a difficult diagnostic problem to the medical man, and while the specialists in nervous diseases are far from comprehending the significance of the

various forms of headache, they can be classed roughly according to certain broad rules. Dr. Head does this in the paper referred to. Many medical practitioners do not differentiate between the different kinds of headache, or at least do not apply to them their diagnostic significance. Some even treat a headache as if all pains in the head were of similar diagnostic import. It goes without saying that early diagnosis, diagnosis early enough to prevent the affection from going farther, is very difficult, frequently impossible even when the general practitioner is sufficiently well trained in early symptoms and signs and their significance. But it seems that a good deal can be done in that direction. Early diagnosis and proper treatment is the really scientific preventive medicine, which is said to be the medicine of the future.

INGUINAL EPIDERMOPHYTIA.

Since the war a dermatosis has become singularly frequent, namely, the mycosis first described by Hebra under the name of *eczema marginatum*, or *tinea cruris*, whose causal agent is the epidermophyton discovered by Sabouraud. The affection has a predilection for the inguinal region, but is not confined to it, because it is also frequently found in the folds of the axilla. The process may also develop around the umbilicus and even in various degrees on the trunk and limbs, principally the lower limbs.

When it occurs in the inguinal folds, it begins on the thigh, in the immediate neighborhood of the fold, in the form of a red, dry, irregularly rounded spot, extending over the thigh and the genitalia and presenting a variable aspect after fifteen or twenty days. At times it is of an intense red color, dry, smooth, and glistening, slightly desquamated at the centre and marked off by a slightly raised border, and presents a thin white squamous area about two millimetres within the border concentric to it. At other times the color of the central portion, much less marked, is slightly fawn yellow, the borders rose colored and less projecting, and immediately within the borders a continuous zone two to three millimetres broad is seen, made up of fine, thin, white scales that are more or less detached. Sometimes instead of one squamous border there are two concentric ones about two millimetres apart, thus forming a cockade.

Usually round, the patch may be bilobate or trilobate, and sometimes at a short distance from it will be found clustered together regularly shaped circles having the same appearance and varying in size from a pea to a ten cent silver piece. On the scrotum and labia majora the lesion assumes a dif-

ferent aspect. On account of its pale rose color it is hardly noticeable, but it manifests itself by a thin, fine grayish white desquamation, forming a rounded sinuous outline, recalling the gray tint which characterizes cutaneous lesions in the negro.

The plaques extend to the suprapubic region only exceptionally and join together on the median line. Less infrequently they extend to the posterior aspect of the scrotum, over the perineum and around the anus, and cease at the upper portion of the intergluteal fold. In all these regions the lesions are superficial, pale red in color, and their limit usually marked by a border of desquamation. They are invariably dry.

The second site of election for epidermophytia is the axillary region, where the spots, rather bright red in color, rounded, distinctly limited, with a marked desquamative aspect, are frequently multiple and, by their cohesion, form plaques having a polycyclical contour. They occupy the axillary hollow. Localization around the umbilicus is much less common. It manifests itself by a rounded patch, with a distinctly limited border, with or without fine desquamation, often measuring as much as twenty or more centimetres in diameter, sometimes concentric to the umbilicus, at other times more or less eccentric to it. The plaques developing on the trunk and segments of the limbs are also rounded in outline, with a bright red surface, and slightly raised distinctly marked edges closely surrounded by a more or less marked collar of desquamation. Epidermophytia is always accompanied by pruritus, especially nocturnal, which occurs at the onset of the lesion and persists while recovery is taking place. The process may last a year if not treated with regularity, but after a certain time it ceases to spread. Appropriate treatment results in a rapid recovery.

The diagnosis is usually easy, but in doubtful cases recourse should be had to the microscope. The intertrigo set up by perspiration occupies the inguinal folds, but the lesion has a less regular configuration, undergoes evolution quickly, and is accompanied by a manifest oozing. The same may be said of eczema of the region. Psoriasis, when it develops in the inguinal area, is covered by desquamation which is made more distinct by scratching, and if this is continued characteristic minute droplets of blood will be seen to appear. In circumscribed lichen the color is paler, the surface of the lesion is more brilliant and typically plaided. In erythrasma, the long duration of the affection, the yellow color of the plaques, their irregular configuration with finely insular borders, and the absence of any raised surface make the diagnosis easy.

In doubtful cases the epidermis should be superficially scraped at the border of the lesion, the product placed on a slide and a few drops of a forty per cent. potash solution added. Cover with a slide, beat slightly and the mycelian filaments can be seen composed of quadrangular cells having a double contour. These elements are seen in the midst of the epidermic cells and, contrary to trichophytosis, they are invariably absent on the hairs.

Epidermophytia is rare in ordinary times but during the war it was frequent. It was often transmitted by direct contagion, sometimes during coitus. Lack of bodily cleanliness is also a factor in its production, and it would seem that the disease can be transmitted by the underclothing when not properly dried. Treatment consists of repeated applications of tincture of iodine diluted to one-third strength with friction over the surface of the plaques. It should be repeated every second day for ten to twelve days. As to the pruritus, it can be relieved by a lotion of menthol in alcohol diluted with a one per cent. watery solution of carbolic acid.

News Items.

Dr. Robinson and Dr. Turner Elected.—Dr. G. Ernest Robinson and Dr. John P. Turner were elected associate chief surgeons of the Frederick Douglass Hospital, Philadelphia, at a staff meeting on July 30th.

Award of Riberi Prize.—The Riberi prize of the Royal Medical Academy of Turin has been awarded to Dr. Giuliano Vanghetti for his work in connection with the utilization of the muscle of a stump to actuate an artificial limb (cineplastic operation).

Austrian Children in Desperate Condition.—Austria has asked Switzerland to feed 45,000 Austrian children for six weeks. The children, it is declared by medical men, will either perish outright or grow up weaklings unless they get a change and proper food.

Jewish Memorial Hospital to Move.—The Jewish Memorial Hospital, formerly the Philanthropin Hospital, has purchased the Inwood House at 202nd Street and Broadway, New York. This institution will be renovated to accommodate 150 patients and is expected to be open by June 1, 1921, when it will demonstrate the possibilities of an open hospital.

Vera Cruz Port to Reopen.—The port of Vera Cruz has been reopened under a modified quarantine against bubonic plague. Regulations were drawn up by Dr. Carl Michel, of the U. S. Public Health Service, and Mexican health authorities. A campaign against yellow fever will be begun at Vera Cruz under the advisory supervision of Dr. Michel, along the lines of the United States campaign in Cuba and Panama.

Royal College of Surgeons Fellowship to Americans.—The Honorary Fellowship of the Royal College of Surgeons was formally presented on July 8th to four distinguished surgeons: Professor John Finney, of Johns Hopkins University; Dr. Charles H. Mayo, of Rochester, Minn.; Professor A. Depage, of Brussels, and M. Pierre Duval, of Paris.

School of Röntgenology.—The special committee of the New York Association for Medical Education has drawn plans for a course of instruction in röntgenology. The July 15th *Bulletin* of the Association states that one of our universities has expressed a willingness to open and develop such a department; one of the leading physicists of the country and a staff of the best röntgenologists of New York have agreed to serve as a teaching body and that provision of a comparatively small sum of money to purchase equipment and start the work is all that is necessary to launch this excellent and sorely needed new department of medical education.

American Hospitals in Near East.—An American hospital of one hundred beds has been established in Stamboul, the Turkish section of Constantinople. Dr. A. R. Hoover, a resident of Turkey for many years, will be the director, and Dr. Elfie Richards Graff, formerly physician to Vassar College and a member of the Wellesley unit of the American Committee for Relief in the Near East, will be his assistant. Equipment for the hospital will be supplied by the American Red Cross and the personnel by the Red Cross and the American Committee for Relief in the Near East. Constantinople College for Women will open a school for nurses in connection with the hospital and within a year will open a woman's medical college.

An open air hospital for tuberculous children has also been established on the shores of the Bosphorus, a few miles north of Constantinople, under the direction of the American Committee for Relief in the Near East. Dr. Elfie Richards Graff is the director.

Died.

ALTHANS.—In New York, N. Y., on Tuesday, August 3d, Dr. Charles H. Althans, aged eighty-three years.

ASHER.—In New Orleans, La., on Monday, July 5th, Dr. Philip Asher, aged fifty-three years.

BORNIO.—In New Orleans, La., on Saturday, July 17th, Dr. Domingo Bornio, aged sixty years.

FURTFNEY.—In Orosi, Cal., on Wednesday, July 21st, Dr. Henry Furtney, aged sixty-three years.

HENRY.—In Lecompte, La., on Wednesday, July 7th, Dr. Eugene L. Henry, aged forty-six years.

LEWIN.—In Buffalo, N. Y., on Saturday, July 31st, Dr. William C. Lewin, aged fifty-seven years.

LEWIS.—In Harrington, Del., on Sunday, August 1st, Dr. Beniah L. Lewis, aged seventy-two years.

MCVEA.—In Baton Rouge, La., on Monday, July 5th, Dr. Charles J. McVea, aged fifty-one years.

MEIERHOF.—In New York, N. Y., on Thursday, August 5th, Dr. Harold Lee Meierhof, aged twenty-six years.

MOYER.—In Lansdale, Pa., on Tuesday, August 3d, Dr. Samuel C. Moyer, aged seventy-four years.

ROBIN.—In New Orleans, La., on Saturday, July 10th, Dr. Ernest A. Robin, aged fifty-one years.

SEVERANCE.—In Keeseville, N. Y., on Wednesday, July 28th, Dr. Karl J. Severance, aged fifty-four years.

Book Reviews

LOCAL ANESTHESIA.

Die örtliche Betäubung, ihre wissenschaftlichen Grundlagen und praktische Anwendung. Ein Handbuch und Lehrbuch. Von PROF. DR. HEINRICH BRAUN, Geh. Medizinalrat, Direktor des Krankenhauses in Zwickau. Fünfte, ergänzte und teilweise umgearbeitete Auflage. Mit 208 Abbildungen. Leipzig: Johann Ambrosius Barth, 1919. Pp. xvi-507.

This fifth edition contains two new chapters dealing with operations on the throat and on the vertebral column and thorax. In the chapter on throat operations, the most extensive operative procedures are described, including strumectomy, laryngectomy, adenectomy, and resection of the pharynx and esophagus under conductive local anesthesia. The details of paravertebral anesthesia are given in the chapter on thoracic surgery and it promises to be of great value in abdominal operations. Breast cancers may be removed under local anesthesia. The chapters on operations of the abdomen and on the genitourinary organs and rectum have been rewritten and the whole work has been brought up to the minute in conformity with the most modern practice.

The first half of the book deals with the history, theory and physiological principles of local anesthesia, the use of cocaine and its toxicology, and also of the other local anesthetics, such as tropacocaine, eucaine, holocaine, the orthoform group, stovaine, alpine, novocaine, phenol, quinine and urea hydrochloride, and other preparations not so well known or used in this country. The author prefers the use of novocaine with adrenalin as the most useful of them all. The various methods of local anesthesia are described in detail. It is the author's opinion that the belief that children and nervous adults are not amenable to local anesthesia is no longer tenable because of the improved modern technic. He has operated upon children four years old under local anesthesia with the aid of cajolery and bribery. The indications and technic of infiltrative and conductive anesthesia are fully described.

The illustrations are profuse and illuminating, in many cases being actual photographs of operative field. The bibliography is most exhaustive and up to date. On the whole, the book is a valuable adjunct to the armamentarium of the general surgeon and the specialist, and of distinct value as an aid to the student.

HEREDITY.

Heredity and Social Fitness. Study of Differential Mating in a Pennsylvania Family. By WILHELMINE E. KEY. With Charts. Washington, D. C.: Carnegie Institute, 1920. Pp. 102.

More than a century ago, there came to Western Pennsylvania a German with his wife and three children, and about the same time, three married German brothers. They all acquired land there seemed no obstacle to their proving a blessing to their adopted country. Some have; but tracing the defectives, as they drifted from place to place in Pennsylvania, these have been found to constitute the dregs of every community. The author has undertaken the tremendous task of tracking some 1,822 members of the two families, not with a view to exhibit her

talent for such research or to prove the depravity of man, but simply to show how the histories of the various branches affect the immigration problem of today, and how far these two branches assimilated and amalgamated, seeing they were planted in a progressive, pioneer community where democratic ideals prevailed and opportunities for education were fair. There was amalgamation, but, then as now, the defective members married defective natives or incoming immigrants, while the superior ones had wives from the better native strains. The modern inrush of immigrants meets conditions far less favorable than it did a century ago; Ellis Island, after all, can only judge superficially, and the need for colonization schemes for the unfit is increasing. The author suggests five main remedial measures: segregation and even sterilization of the grossly defective; state control of marriage through a eugenics board; Federal control of immigration; creation of an enlightened public sentiment in favor of eugenic mating, and eugenic education of prospective couples. All this ought to be supplemented by studies abroad to prevent the transplanting of strains seriously defective, and by studies here to secure the locating and registration of the increasingly unfit. One reads of vital statistics, and the reader of this book will find the facts very alive, very impressive, even tragic, not inclining the flippancy to say with the Irishman, "What has posterity done for me that I should do anything for posterity?"

LEONARD MERRICK.

When Loves Flies Out o' the Window. By LEONARD MERRICK. With an Introduction by W. ROBERTSON NICOLL. New York: E. P. Dutton & Co., 1920. Pp. x-309.

The Worldlings. By LEONARD MERRICK. With an Introduction by NEIL MUNRO. New York: E. P. Dutton & Co., 1919. Pp. v-334.

Leonard Merrick is a writer who for a long time was not appreciated by anyone but the literary critics and who is now being pushed into public favor by the cumulative acclaim of his fellow craftsmen. His works are being brought out in a new American edition with prefaces by various writers attesting to Mr. Merrick's artistry, and the public is finding out that in spite of this they are splendid entertainment. Merrick's stories—and the two novels mentioned are preeminently stories—are light in theme, expert in workmanship, and disillusioned in mood. There is no padding in them and no undigested psychology. They might be used as models for college courses in composition.

Mr. Merrick is most at home in the theatrical and literary worlds and his novel *When Love Flies Out o' the Window* bears the earmarks of experience. There is more than a touch of irony in his depiction of the noted author who was lauded by all the critics but whose sales did not warrant his publishers advancing fifty pounds on account. He knows, too, the precarious life of the chorus girl—one day with an engagement, the next without—and the hopelessness which makes her snatch at any sort of chance. *When Love Flies Out o' the Window* details the story of a stranded writer and a stranded singer—how he rescued her from the cab-

aret in Paris where she was singing, how they were married on the strength of the two guineas weekly furnished by his *causerie* for a London paper, and how the two guineas suddenly stopped. Mr. Merrick has done a fine piece of work in the portrayal of Lingham's endeavor to prevent his wife's returning to the stage, of his struggle when circumstances finally compelled her to, and of the bitterness which caused their parting—all because Lingham could not see her as a comrade to share the downs as well as the ups of their economic life. The book is written with a fine economy of means: there is not an unnecessary incident to mar the course of the narrative, not a shade too much interest on the part of the author in any one character or situation, and the happy end is not an afterthought.

The Worldlings is a melodrama in which the hero and the villain are the same person. There is nothing new about the theme—the impersonation of the prodigal son by an adventurer who succeeds in his bluff, marries the beautiful daughter of a neighboring countess, and is discovered only because his partner in the plot turns upon him. But Mr. Merrick's people are not thus easily disposed of: they cannot be sharply separated into the sheep and the goats. The original prodigal son is a waster, and the man who takes his place is a rather fine fellow who had neither the luck nor the hard-headedness to succeed in life. The countess's daughter is a cool, artificial beauty, but when the veneer cracks she is much the same as other women. Even Blake's fellow plotter is moved by much the same springs of ambition as distinguish more laudable enterprises. *The Worldlings* should appeal to many readers. Those who demand incident will find it a compact, quickly moving story which holds the interest from cover to cover, while those who can see beyond the plot will admire the skill with which Mr. Merrick has clothed a conventional theme with the flesh and blood of reality.

WAR NEUROSIS IN FICTION.

Peter Jameson. By GILBERT FRANKAU. New York: Alfred A. Knopf, 1920. Pp. i-431.

Gilbert Frankau's novel fulfills the requirements of the postwar fiction readers. It describes the war not too attractively, yet not too uncomfortably, and the characters of the book are just such wholesome, fine individuals as the secretly self-discontented reader would like to be. The business man and woman will delight in reading of the adventures of a man, essentially a business man, who tottered on the brink of ruin because he answered the call of war, and yet just survived—not in his business, from which he escaped unscathed, however, but in his comfort and future. The longing for adventure and romance in business that has not found achievement in us, animates the pages, rendering the hero's tobacco industry so absorbing to him that his wife and family are forced into the background.

Returning from the war, a war neurosis victim, Peter Jameson has to pass through the conventional struggle of adjustment to a world where business has lost its urgency, where the human beings in the tale have a romance and value of their own. Peter's father-in-law, the skilled neurologist, is able,

by psychoanalysis to suspect and guide him through this period of adjustment, and the story ends with Peter's gratifying response to the call of the soil.

England, we foresee, is safe, with her sons returning to mother earth. This amateur farmer, probably because he knows his business, somehow succeeds on the large scale of his other business enterprises. Romance and adventure even though it be only in the growing of crops once more lend the scene a rosy glow.

NIETZSCHE.

The Antichrist. By F. W. NIETZSCHE. Translated from the German. With an Introduction by H. L. MENCKEN. New York: Alfred A. Knopf, 1920. Pp. vii-182.

Poor Nietzsche! How he hated those who included the word pity in their vocabulary and yet how can one help pitying him! The cause of this was the turn of circumstance, his ill fitting personality, a heritage of ministerial ancestors, and the curse of syphilis. No wonder he stood on the edge of the world and howled. With his inferiority which he strove to overcome his wit sharpened, and often while he was baying at the harmless moon he told of things we knew were true. He spoke of the moon's dull light and of how it differed from the sun. Many were struck by his obvious truths, others were convinced by his keen judgments and attempted to swallow his creed, but they found more condiment than meat in the dose.

We are indebted to Nietzsche for many bright and truthful sayings, boldly told. When we examine his bravery with a bit of care we find it no more than coward's courage. The only way his works can be read with profit is by an impartial separation of the grain from the chaff. All prejudice must be cast aside and we must soften our judgments and consider how he labored under many handicaps, ever seeking an external cause for his own misery and a reason for his insolvent soul. He found little good in man and even less, by his own confession, in woman. Had he looked more into his own egotistical being he would perhaps have found the causes for his shortcomings and refrained from damning the world, its inhabitants, and their ideas, even if many of them were erroneous and childish. We must also search for the motive of fear that prevented him from finding the good in man. Was it that he trembled at losing the protective armor that prevented him from coming into contact with his fellow man? Most likely.

With all this we owe the man a debt. Just as Napoleon's weakness led him on to a tremendous striving without peace to himself and to great creative achievements, so it was with Nietzsche. We cannot afford to cast him aside and let his little liked mannerisms keep us from the many fundamental teachings he left. It is only a question of realization that many beautiful flowers and useful foods owe their existence to manure. The difficulty is that few of us relish the task of the horticulturalist, especially when the fertilizer has a strong stench as of ground bone dust. We must not make the error of calling him Teutonic and carelessly cast him aside. He was of Polish origin. This should not influence us one way or another for the seekers after truth

have no scruples in borrowing their material wherever they find it.

Just what Menken's idea was in writing an elaborate preface is a bit difficult to determine. Perhaps he wished to identify himself with a really great man and immortalize himself by being bound into one volume with the pugnacious Nietzsche. He can best answer this himself, for he is still among the living.

O. HENRY PRIZE STORIES.

O. Henry Memorial Award Prize Stories 1919. Chosen by the Society of Arts and Sciences. With an Introduction by BLANCHE COLTON WILLIAMS. Garden City and New York: Doubleday, Page & Co., 1920. Pp. xvii-298.

This volume of stories has been selected as the best short stories that have appeared in American publications. Aside from the interest they offer and the pleasure one may get from reading carefully selected short stories they offer an added value in being a permanent index for reference of what American writers are doing. It is stated that there has been a dearth of short stories during the past year. This should be referred to as being relative, for in no country are there so many short stories written. The demands made by the numerous magazines are tremendous and they must be filled. The editors find it difficult to secure enough copy and yet keep a high standard. It may be well to amend the statement and say that the number of good short stories is limited, that the standard is none too high. It may seem strange where so many are being produced that so few are of a really high standard. In view of these facts it is commendable that we have a volume containing the cream of what has been produced.

Worthy of note are the prize story, *England to America*, by Margaret Prescott Montague, and the *Porcelain Cups* by James Branch Cabell. Cabell has come to the fore and he has received recognition from his much discussed *Jurgen*. He has great charm and more depth than is apparent at first glance, both from the material which he handles in a masterly way, material that he has culled from the literature little appreciated in America, and from the subtle irony which he weaves into his stories.

This is, indeed, a splendid book for vacation reading, or for whiling away an idle half hour. We are presented with stories of good workmanship, wide interests, and not too banal.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

FAIRY TALES FROM FRANCE. Retold by WILLIAM TROWBRIDGE LARNED. Illustrations in Full Color. By JOHN RÆ. New York, Chicago, and Toronto: P. F. Volland Company.

TRAVAUX NEUROLOGIQUES DE GUERRE. Par GEORGES GUILLAIN, Professeur agrégé à la Faculté de médecine de Paris; Médecin de l'hôpital de la Charité; et J. A. BARRÉ, Professeur de Neurologie à la Faculté de médecine de Strasbourg. Préfacé de Professeur PIERRE MARIE. Paris: Masson & Cie, 1920. Pp. xii-463.

WHEN LOVE FLIES OUT O' THE WINDOW. By LEONARD MERRICK. With an Introduction by W. ROBERTSON NICOLL. New York: E. P. Dutton & Co., 1920. Pp. x-309.

BARNES UTSÅTTANDE FÖR TUBERKULÖS SMITTA. AV EMANUEL BERGMAN; Medicine Licentiat av Göteborgs Nation. Uppsala: Appelbergs Boktryckeri Aktiebolag. Pp. vii-126.

GENERAL PSYCHOLOGY. By WALTER S. HUNTER, Professor of Psychology, University of Kansas. Illustrated. Chicago: The University of Chicago Press. Pp. xiii-351.

NUEVAS, ORIENTACIONES SOBRE LA PATOGENIA Y TRATAMIENTO DE LA DIABETES INSIPIDA. Par Dr. GREGORIO MARAMON, de Hospital General. Madrid: Editorial Saturnino Calleja, S. A., 1920. Pp. xiii-174.

RADIOGRAPHY IN THE EXAMINATION OF THE LIVER, GALL-BLADDER, AND BILE DUCTS. By ROBERT KNOX, M. D., Hon. Radiographer, King's College Hospital, London. A Series of Articles Reprinted from *Archives of Radiology and Electrotherapy*. Illustrated. St. Louis: C. V. Mosby Company, 1920. Pp. i-64.

A MANUAL OF NEURASTHENIA. (Nervous Exhaustion.) By IVO GEIKIE COBB, M. D., M. R. C. S., Neurologist, Ministry of Pensions; Late Assistant to Out Patient Physician, the Middlesex Hospital; Formerly Neurologist, Brinnington Section, Second Western General Hospital. New York: William Wood & Co., 1920. Pp. xvi-366.

X RAY OBSERVATIONS FOR FOREIGN BODIES AND THEIR LOCALIZATION. By Captain HAROLD C. GAGE, A. R. C., O. I. P., Consulting Radiographer to the American Red Cross Hospital of Paris; Radiographer in Charge, Military Hospital V. R. 76, Ris Orangis, and Complementary Hospitals. Illustrated. St. Louis: C. V. Mosby Company, 1920. Pp. i-83.

EPIDEMIC ENCEPHALITIS. (Encephalitis Lethargica.) By FREDERICK TILNEY, M. D., Ph. D.; Professor of Neurology, Columbia University; Attending Neurologist, the Presbyterian Hospital and the New York Neurological Institute; Consulting Neurologist, Roosevelt Hospital, New York, and HUBERT S. HOWE, A. M., M. D.; Instructor in Neurology, Columbia University; Assistant Visiting Neurologist, the Presbyterian Hospital, New York. Illustrated. New York: Paul B. Heeber, 1920. Pp. xv-252.

DISEASES OF CHILDREN. Presented in Two Hundred Case Histories of Actual Patients Selected to Illustrate the Diagnosis, Prognosis and Treatment of the Diseases of Infancy and Childhood, with an Introductory Section on the Normal Development and Physical Examination of Infants and Children. By JOHN LOVETT MORSE, A. M., M. D.; Professor of Pediatrics, Harvard Medical School; Visiting Physician at the Children's Hospital, and Consulting Physician at the Infants' Hospital and at the Floating Hospital, Boston. Third Edition. Illustrated. Boston: W. M. Leonard, 1920. Pp. v-639.

ORAL SURGERY. A Treatise on the Diseases, Injuries, and Malformations of the Mouth and Associated Parts. By TRUMAN W. BROPHY, M. D., D. D. S., LL. D., Sc. D., F. A. C. S., President and Professor of Oral Surgery, Chicago College of Dental Surgery; Oral Surgeon to St. Joseph's, Michael Reese, and other Chicago Hospitals; Consulting Oral Surgeon to the Presbyterian Hospital, etc. With Special Chapters by MATTHEW H. CRYER, M. D., G. HUDSON MAKUEN, M. D., WILLIAM J. YOUNGER, M. D., F. W. BELKNAP, M. D., CALVIN S. CASE, M. D., D. D. S. With Nine Hundred and Nine Illustrations, Including Thirty-nine Plates in Colors. Philadelphia: P. Blakiston's Son & Co., 1918. Pp. xvi-1090.

TRAITÉ D'ANATOMIE HUMAINE. Par P. POIRIER-A. CHARPY. Nouvelle édition Entièrement Refondue. Par A. NICOLAS, Professeur d'Anatomie à la Faculté de Médecine de Paris. Avec la Collaboration de MM. O. AMOEDO, ARGUAD, A. BRANCA, R. COLLIN, C. GUNEO, G. DELAMARE, PAUL DELBERT, DIEULAFE, A. DRUAULT, P. FREDET, GLANTENAY, A. GOSSET, M. GUIDE, A. HOVELACQUE, P. JACQUES, A. PRENANT, H. Système veineux: A. CHARPY (revision A. Hovelacque). Structure des veines: P. JACQUES (revision R. Arguad). Veines: A. CHARPY (revision A. Hovelacque). Troisième édition Revue. Avec 99 Figures dans le Texte, en Noir en Couleurs. Paris: Masson et Cie, Pp. i-278.

Miscellany from Home and Foreign Journals

General Anesthesia with Ethyl Chloride in Fractional Amounts.—Paul Lutaud (*Journal de médecine de Paris*, January 20, 1920), from experience in war surgery, comments on the disadvantages of ether, chloroform, anesthetic mixtures, and other procedures, in particular as regards slowness of induction, ten or fifteen minutes always elapsing before the operation could be started. Ethyl chloride is highly advantageous in this and other respects, but as applied hitherto, yields only a brief anesthesia. Lutaud uses a metallic mask of medium size, closely adjusted to the face with an inflatable rubber margin, and provided within with wire netting to which gauze is fastened, and above with a small funnel shaped projection, open at the top and communicating with the interior of the mask. The mask is placed in firm contact with the face, the patient directed to breathe out completely two or three times, and an ordinary ethyl chloride or kelene tube passed into the funnel shaped opening. The stream of ethyl chloride moistens the gauze within. Anesthesia is generally obtained in one minute; the ethyl chloride tube is then removed and the funnel shaped opening closed with the finger tips. For prolonged anesthesia only about one-fifth of a twenty mil tube of anesthetic is at first used. The anesthetist then closes the opening, while keeping the mask firmly against the face, and later renews the dose of ethyl chloride according to requirements. With this procedure the patient shows much less cyanosis than where a larger amount is used at the outset, and the anesthesia can readily be kept up for ten or fifteen minutes, a little air being allowed between successive doses of the anesthetic, provided, however, complete resolution has been obtained at the outset. Under this type of anesthesia the author removed over a thousand projectiles with the x ray screen, and did several hundred operations on wounds, including short bone operations, such as compound fractures and ligations. In abdominal work the incision was made under ethyl chloride, the abdominal cavity explored, and the anesthesia then discontinued during such maneuvers as intestinal suture, being later resumed for closure of the incision. A gastrostomy, two gastroenterostomies, two artificial anus operations, acute and chronic appendicitis procedures, and even removal of a malignant ovarian cyst in a countrywoman, were successfully performed under ethyl chloride.

Pyelotomy and Nephrectomy.—Daniel N. Eisendrath (*Annals of Surgery*, June, 1920) from a study of the variations and anomalies of the renal vessels suggests the following changes in operative technic:

1. During nephrectomy or even nephrotomy the poles of the kidney should be most carefully exposed. The mobilization of the kidney should be gradual, care being taken both at the lower and upper poles never to tear or divide adhesions or strands of fibrous tissue before they have been inspected and also palpated (for a possible pulsation) to exclude the presence of a supernumerary

vessel. I have found the suggestion of Kolisher an excellent one, namely, to divide the ureter in nephrectomy before attempting to mobilize the kidney.

2. In pyelotomy one must bear in mind the anomalies of the retropelvic vessels which I believe have been reported for the first time in this paper. Careful exposure of the pelvis before the incision for delivery of a calculus is made will greatly lessen the chances of encountering an anomalous vein or artery.

Treatment of the Acute Abdomen.—J. P. Runyan (*Southern Medical Journal*, February, 1920) has formulated the following conclusions from the answers received to a questionnaire sent to a number of prominent surgeons:

1. It is a safe and sane procedure to operate early in an attack of acute suppurative peritonitis.

2. After the stage of contamination comes the stage of diffuse peritonitis, in which the Ochsner treatment offers the largest proportion of recoveries.

3. The exceptions to rule two are perforation of duodenal ulcer and gunshot wounds of the hollow viscera.

4. Do not hurry too much to operate once the Ochsner treatment has been started.

5. Following the Ochsner treatment, an operation should be done and Crile's principles applied in the aftertreatment of all cases of septic peritonitis.

6. Where there are large areas of denuded peritoneum, from which may be expected a considerable flow of pus and serum, gauze drainage after the manner of Mikulicz or Price may be expected to give the most satisfactory results.

7. In cases in which no peritoneal denudation has occurred, rubber tube drains will suffice.

Amputation of the Leg.—O. Borchgrevink (*Annals of Surgery*, June, 1920) describes the operation which he follows for the amputation of the leg as follows:

From a point eight cm. above the line where the tibia is to be divided, make a longitudinal incision through the skin and superficial fascia three cm. behind and parallel with the fibula. The incision is curved forward above the head of the fibula. Place clips on the edges of the superficial fascia. Divide the peroneal nerve behind the head of the fibula, expose it upward; reflect its divided end and push it upward behind the biceps tendon. Divide the tendon of the biceps and the collateral fibular ligament as close to the fibula as possible without injuring its periosteum. Open the tibiofibular joint and free the head of the fibula, which is removed after division of the neck of the bone. Do not injure the insertion of the biceps tendon into the external tuberosity of the tibia. To prevent injury of the anterior tibial artery and vein, expose them at their passage under the fibula. Separate the interosseous membrane from the shaft of the fibula. Be careful neither to injure its periosteum nor the main vessels.

Divide the fibula at the lower end of the incision. From the inner and front side of the leg make a flap consisting of skin and superficial fascia. The flap must at least be five cm. longer than the diameter of the leg at the joint chosen for the division of the tibia. At the same level join the upper ends of the flap incision by a horizontal incision around the outer and posterior part of the leg. Divide the fibula two to three cm. above the last incision. Treat both ends of the left piece of the fibula according to Hirsch-Bunge. Divide the muscles at the line chosen for the section of the tibia. Divide the tibia and remove its periosteum and marrow for one and five tenths to two cm. upward. With the standing patient the sawn surface of the tibia must form accurately a horizontal plane. Its edges should be rounded with a file. Every point of the end of the tibial stump must bear, and bear equally much. Carefully close the incision of the superficial fascia by a separate catgut suture. Only when the leg stump has a length of at least fifteen cm. there can become a question of leaving a piece of the fibula.

In case of reamputation the fibula is removed in the way above described. If the stump is nonend-bearing, a part of the tibia if sufficiently large for treatment, according to Hirsch-Bunge, is amputated. If the stump is covered with healthy and movable skin and superficial fascia, these should be separated from the bone, but otherwise left as they are. Has the end of the stump a tender and immovable scar, an amputation is sufficient for the covering of the stump with superficial fascia and normal skin is necessary.

Intravenous Injections of Pancreas Emulsions in Experimental Diabetes.—Israel S. Kleiner (*Journal of Biological Chemistry*, November, 1919) administered to dogs rendered diabetic by depancreatization slow intravenous injections of unfiltered water extracts of fresh pancreas, diluted with 0.9 per cent. sodium chloride solution. In nearly all the experiments a substantial reduction in the blood sugar occurred lasting from half an hour to an hour and three quarters. There was also a diminution in the excretion of sugar in the urine. Controls of other gland extracts failed to produce similar results. The author believes that his experiments support the internal secretion theory of experimental diabetes and also thinks that the pancreas emulsions might be used as a therapeutic agent in human beings, although more work will have to be done on this problem before such injections can be carried out safely.

The 1918 Pandemic of Influenza in Canton.—William W. Cadbury (*China Medical Journal*, January, 1920) says that three definite epidemics of influenza appeared in Canton during the spring, fall, and winter of 1918, coinciding in time with the appearance of the disease in Europe and America. In Canton foreigners were but slightly affected. The spring epidemic was mild, the fever lasting but two to four days; the second and third epidemics were more severe, the fever usually lasting four or five days and complicated in some cases by pneumonia. Males suffered more than females. At the Christian College, Canton, the majority of the patients were

boys between eleven and twenty years of age; the older students, the faculty, and the servants were affected in relatively much smaller numbers. Leucopenia was generally present. The fever curve often presented two high peaks from one to four days apart. One attack of the disease tended to immunize against further attacks. The disease tended to run through a household, affecting every member. The mortality in Canton was low.

Injection of Cow's Milk in Ocular Infections.—D. S. Garcia Mansilla (*Revista de Medicina y Cirugia Practicas*, December 14, 1919) states that this method of using cow's milk by injection was first used by Müller and Thanner in Vienna in 1916, not only for the treatment of ocular infections but also general infections such as influenza, bronchopneumonia, gonorrhoea, and articular rheumatism. The eye infections where the method has been found of value are acute iritis, infected ulcers of the cornea, postoperative infections, purulent ophthalmia, trachoma, and eczematous keratitis. The injections are given intravenously, subconjunctivally, or intramuscularly; the quantity being about five c.c. and the interval averaging two days.

Icebox Fixation Method in the Performance of the Wassermann Reaction.—R. G. Owen and F. A. Martin (*Journal of Laboratory and Clinical Medicine*, January, 1920) believe that a simple alcoholic extract of human heart with the first phase of the reaction carried out at 7 to 10° C. for four to six hours gives the most reliable Wassermann results. Like other observers, they obtained false positives in a considerable number of cases when cholesterinized antigens were used. The sera from 1,113 patients was examined with plain antigen at 7 to 10° C. fixation for four hours, and with incubation at 37.5° C. for one hour with both plain and cholesterinized antigen. Fewer doubtful reactions were obtained by the icebox fixation method than with the older methods.

Dislocation of the Shoulder Joint and Its Treatment.—Alan H. Todd (*Practitioner*, March, 1920) asserts that the present aftertreatment of dislocations of the shoulder by fixation of the arm to the side is irrational, unscientific, and unsuccessful, resulting in limitation of abduction and osteoarthritis. In rectangular abduction the rent in the capsule is closely coaptated, whereas in adduction the capsule is crowded together in a crinkly lump and coheres in that position, thus limiting abduction and causing pain. The arm is no more likely to redislocate when placed in rectangular abduction than when it is tied to the side. If abduction is adopted, the resulting movements are much better; they are obtained much more quickly and less painfully.

New Treatment of Chronic Suppurating Otitis with Dakin's Solution.—D. A. Ramos Acosta (*Revista de Medicina y Cirugia Practicas*, January 28, 1920) has found that Dakin's solution is an excellent agent for the rapid cure of chronic suppurating ears. Having eliminated all nasopharyngeal causes of ear discharge, this method should be the one of choice; further, it has no contraindications. To avoid irritation of the auricle it should be anointed with vaselin.

Proceedings of National and Local Societies

MEDICAL SOCIETY OF THE STATE OF
NEW YORK.

*One Hundred and Fourteenth Annual Meeting,
Held in New York, March 23 to 25, 1920.*

The President, Dr. CLAUDE C. LYTLE, of Geneva, in the
Chair.

(Continued from page 1054, Vol. CXI.)

SECTION IN SURGERY.

Abdominal Incisions.—Dr. CHARLES W. HENNINGTON, of Rochester, stated that there was still a great difference of opinion in reference to abdominal incisions. The final decision as to which was best would be reached by a further study of the normal healing of tissues. In general, the location and direction of the incision ought to be determined by its effect on the muscles and innervation. The approach to this question depended upon anatomical and embryological considerations. He felt that many of the objections recently raised to the McBurney incision would vanish if attention were paid to the complete and orderly separation of the layers. Whether the high or low McBurney incision was to be employed must be determined by examination and final palpation when the patient was under the anesthetic. The low incision was preferable, in his opinion, as it gave better access to the abdomen. The occurrence of hernia after the McBurney incision was due to needless destruction of the innervation. The other lateral incision was that through Petit's triangle, with a similar spreading of the muscles. This afforded a good approach to the retroperitoneal appendix and to the kidneys and ureter. This incision had the advantage that it admitted of excellent closure and disturbance of the innervation could be avoided with moderate care. The transverse incision had been slow in gaining favor, and justly so, in his opinion. Although the transverse incision permitted a wider exposure, the muscle fibres of the rectus muscle were longitudinal; furthermore, the transverse incision did not readily lend itself to enlargement of alteration, and the difficulties of closure outweighed those encountered when the muscle was divided longitudinally. The best way of closing the transverse incision was by the crossbuck mattress suture. The best approach to the lower abdomen was by the classical longitudinal midline incision. There was of course, greater danger to the innervation from a long than from a short incision. The toxicity absorbed might be just as great from a short incision as from a long one. A wound with bruised edges, even if short, might give a greater degree of toxicity than a long one with clean, unbruised edges. In closing any incision, emphasis was to be laid on the exact approximation of similar structures. The explanation of painful scars was dependent upon one of two factors, the inclusion of nerves in the scar, or traction produced by tension on the scar. He had had a special opportunity of observing scars in France, as where he was located, a considerable number of soldiers had

been sent back from base hospitals because of painful abdominal scars, and these men proved a serious problem. It was a question whether they could be sent back as Class A men. Many hernia operations had been done in camps in the United States and it would be interesting to know the exact proportion of these men who were really fitted for Class A military service. He was confident that a large number of these repairs had failed to make Class A men, and he thought they should be placed in Class B limited service. The fact that many men who had had operations for hernia, as well as those having undergone other abdominal operations, complained of painful scars gave weight to the idea that excessive scar formation was to be avoided. In closing an abdominal wound, the aim should be not merely the avoidance of hernia but actual normal anatomical and physiological restitution of the abdominal covering.

The Symptomatology of Perforated Duodenal Ulcer.—Dr. ROBERT S. MACDONALD, of Plattsburg, said that of all the acute abdominal catastrophes, perforated duodenal ulcer was the most painful. In subacute and chronic perforations there was a gradual increase in the symptoms, but in acute perforation the onset was absolutely sudden and the signs pointed toward the duodenum. In non-perforating duodenal ulcer the symptom complex was so complete that, as Doctor Deaver said, the diagnosis could be made over the telephone. In the typical duodenal case there was a history of gastric disturbance extending over a series of years, and often a history of a feeling of fullness in the chest, with eructation of gas, corrected to a certain extent by alkalies. In point of time it was important to remember that the distress occurred several hours after meals and was worse at night; food seemed to relieve the distress. There was a typical loss of weight, mostly in the spring and fall. Vomiting and hematemesis or blood in the stools occurred in eighty per cent. of the cases. There were gastric hyperacidity and hyperperistalsis, and often there was a too rapid expulsion of the barium if no obstruction was present. In many cases the time when perforation would occur could be predicted with considerable accuracy. The anatomical location of the perforation was uncertain. At the time of perforation it was frequently impossible to tell whether it was in the stomach or the duodenum. Often the right side was affected more than the left and this might lead to a mistaken diagnosis of appendicitis, gallstones, or renal colic. The site of the ulcer seemed to make no difference as to the probability of perforation. C. H. Mayo reported 2113 cases of all types, in 84.9 per cent. of which the perforations were duodenal and in 15.1 gastric. The statistics of the Massachusetts General Hospital showed that sixty-nine per cent. of the perforations were duodenal, while Dr. Charles L. Gibson reported that in his cases the majority of perforations were gastric. Doctor Stanton reported seventy per cent. gastric perforation. Of his own ten cases,

three were gastric, five duodenal, and two were in the pyloric area. There was an interval between the early crisis and the later rigidity when it might be possible to get some idea as to the location of the perforation. He felt convinced that seventy per cent. of perforations would be found to occur in the duodenum. The greatest aid in diagnosis was afforded by a well recorded history and a series of x ray findings.

Diagnosis of Cholecystitis and Indications for Cholecystectomy.—Dr. ALEXANDER E. GARROW, of Montreal, said a patient might give a history of cholecystitis and yet the gallbladder show little evidence of disease either to the eye or by palpation. Often such a gallbladder when opened may show a typical strawberry mucous membrane. Frequently the peritoneum in the region of the colon may show hyperemia, and there may be enlargement of the lymph glands in the vicinity of the gallbladder. In fact it might be said that contiguous disease often offered a better criterion for the removal of the gallbladder than the appearance of the organ itself. The evidence seemed to show that inflammation of the gallbladder was infective in origin. We had been taught that infection probably occurred through the bile or from the duodenum by way of the common duct. Drainage of the gallbladder had seemingly benefited a number of patients, but he doubted whether the good results were due to drainage *per se*; probably they were due to rest and the withdrawal of a small amount of bile. Appendicitis, ulcer of the stomach and duodenum, and cholecystitis were largely of embolic origin. Rosenow had shown the selective affinity of the streptococcus for this region, and the bile might be sterile though the wall of the gallbladder was infected. He agreed with those who held that cholecystectomy was the operation of choice, even though there was little pathology limited to the gallbladder itself. When there was a clinical history of recurrent attacks or of a chronic type of inflammation, it was safe to assume the presence of an infective process which became active when the resistance of the body was lowered. Doctor Garrow described various types of cholecystitis and spoke of the difficulty in some instances of differentiating it from duodenal ulcer.

In differentiating perforated duodenal ulcer from acute cholecystitis it might be well to remember that retraction of the abdomen was never seen except in duodenal ulcer. Fever in acute cholecystitis varied with the acuteness of the infection; chills were unusual, being rather more frequent in common duct infection; routine examination of the blood showed a leucocytosis; frequent vomiting was not usual. The indication for the treatment of an acute attack of cholecystitis was drainage, provided bile was found; as long as the bile drained away one might look for recovery, but in many of these cases treated by drainage there were sequelæ and hence many surgeons preferred cholecystectomy. The gallbladder was not essential to life, though it might be a factor in the well being of the individual. The symptoms of chronic cholecystitis were a distressing sensation in the epigastrium, pain beneath the right scapula and over the eighth, ninth

and tenth ribs, a bad taste in the mouth in the morning, and loss of appetite; some individuals were thin and others obese. Inspection of the abdomen was negative, but usually there was marked pain on deep pressure in the gallbladder region. Examination of a test breakfast showed about normal acidity. The gastric symptoms had no direct relation to meals and usually occurred late at night. These patients were often quite comfortable for weeks between attacks. In the ordinary chronic forms of cholecystitis the gallbladder was thickened, milky white in color, and tenderness and rigidity were present; occasionally there was a tumor when the cystic duct was obstructed. Doctor Garrow reported a series of eighty patients operated on for gallbladder disease during the past two years; of these sixty were women. The average age was forty-four and a half years. In forty-five the chief symptom was sour stomach; fifty vomited; twenty-seven were jaundiced; only eleven showed definite rigidity; forty had stones in the gallbladder. A reliable followup was conducted which showed that one had recurrence of symptoms.

Letters to the Editors.

DR. BENJAMIN RUSH.

CHICAGO, July 28, 1920.

To the Editors:

Dr. S. Adolphus Knopf is in error in assuming that Benjamin Rush was the founder of Rush Medical College. Benjamin Rush died in 1813. He was the greatest physician of the five medical signers of the Declaration of Independence, and the first and one of the greatest of American alienists. His work *On the Mind* is still quoted by the foremost European alienists. Next to Chiarrugi and Pinel he was the greatest reformer of the treatment of the insane. Dwight in his *Lives of the Signers* says of Rush: "Although in the political department in which he was called to act there was nothing that furnished occasion for splendid achievements, yet the services he rendered to the country were numerous and valuable; and not less so for being of that humble, unobtrusive character which will not necessarily emblazon his name on the pages of history. With the ardent feelings of an enlightened and inflexible patriot, he espoused the cause of his country, and, with a zeal worthy of such a character, he devoted his best talents to the promotion of its highest interests. And while he is esteemed as a benefactor of mankind, in the valuable contributions he has made for improving and advancing the medical sciences, he will be esteemed no less so by future generations who will learn his real merits from history, for the benefits he conferred on his fellow citizens, in the valuable services he rendered his country as a politician and a statesman." As a statesman, a patriot, a clinician and an alienist Benjamin Rush peculiarly deserves a place in the Hall of Fame.

Very sincerely,
JAMES G. KIERNAN, M. D.

A WORD TO THE GENERAL PRACTITIONER ABOUT THE HANDLING OF EYE CASES.*

By EDWIN B. MILLER, M. D.,
Philadelphia,

Associate in Ophthalmology, Temple University; Assistant Professor of Ophthalmology, Graduate School, University of Pennsylvania; Ophthalmologist to Roosevelt Hospital.

There are two reasons for presenting a paper of this character. First, fifteen or twenty years ago the medical student received a very inadequate course in ophthalmology. Most of these men are poorly equipped to handle eye cases and are so engrossed with their daily tasks that they spend little or no time in study. Therefore, we receive frequent inquiries in reference to the treatment of eye diseases and we see many cases in private practice and in the dispensaries which have not been properly diagnosed and treated. Secondly, while students nowadays receive a fairly comprehensive course, by the time they get into practice they seem to forget a large part of their teaching, as is evidenced by the way in which many of their eye cases are treated and by conversation with patients who have been under their care. If, therefore, this paper will enlighten the first class and refresh the memory of the second, it will be of service to both physician and patient.

RELATIONSHIP BETWEEN THE SPECIALIST AND THE GENERAL PRACTITIONER.

It is often difficult to send patients to a specialist, and probably not one in five go after they are sent, the fear of an excessive fee usually being the factor which keeps them from going. The fault lies with both the general practitioner and the specialist. The medical man does not attach enough importance to such an examination and frequently uses it for moral support only while the specialist often overestimates the value of his services. Both must play fair to each other and to the patient.

I am perfectly sure that many general practitioners hold on to cases which they do not fully understand too long before referring them to a specialist. Many patients have asked me, "Why did not the doctor send me to you sooner?" Sometimes this places us in an embarrassing position and we give evasive answers, but it is still perfectly obvious to the patient that, had an early diagnosis been made

and appropriate treatment given, it would have saved him time, money and discomfort. I have, on the other hand, had patients say to me that they appreciated the promptness of their physician in sending them to a specialist and he would not lose anything by it. I believe it pays to be perfectly frank and open and above board with your patients. I do not believe it does any harm to tell patients that you do not know what is the matter with them but will study up their cases, or call in a consultant, or refer them to someone in the line of work in which you think their case belongs.

There are, however, two sides to every question and many men who profess to be specialists violate the code of medical ethics and take advantage of the general practitioner. I have had men tell me that when they send a patient to a specialist they never see him again. When I was doing general work, I sent patients to specialists who treated them for other conditions which I could have done just as well. I sent a woman to a gynecologist; she was under treatment for some months. She told me she had had two attacks of tonsillitis while under his care and he treated her for it; when I questioned him he said she was in the office and he thought he might as well treat her, admitting that he had forgotten I had sent her to him. That was all wrong and needless to say he received no more of my work. If it is an eye case and the sinuses need looking into, the man who sent the patient should at least be asked to suggest a nose specialist or should be informed of the condition.

We can avoid such tendency toward forgetfulness by having on our cards the name of the doctor who referred the case to us. Even when patients are sent me by opticians, I try to find out who is their family doctor and record it with the optician's name. I frequently find that the doctor has sent them to some specialist, and they have wandered off to the optician. Recently an optician referred a patient to me who also needed medical treatment. I called up her family doctor and explained the situation to him, when he frankly told me that he had sent the patient to another oculist but was glad that the optician was honest enough to refer her to me. He was pleased that I had the case and promised me his cooperation.

I feel that the general practitioner would greatly increase his knowledge, improve his prestige, and add to his income if he would spend three months each year working in the special clinics throughout

*Read before the Kensington branch of the Philadelphia County Medical Society, March 12, 1920.

the city. It would help him to diagnose properly many special cases; it would show him those he could treat successfully; it would give him a different viewpoint of dispensary work, and cause him to discriminate in the cases which he sends to the dispensary. Most clinical chiefs would welcome the coming of physicians to their clinics in this spirit and it would bring about better cooperation between medical men throughout the city. I have advised a number of men to do this and the few who took advantage of the plan tell me that the knowledge gained has been of great value to them.

Now a word or two about the special cases coming to the family doctor for treatment:

Catarrhal conjunctivitis.—There are two forms, acute and chronic. In acute conjunctivitis the symptoms are pronounced and the bulbar conjunctiva is involved, while in the chronic form, the inflammation is usually limited to the palpebral conjunctiva. The objective symptoms are swelling of the lids, abnormal secretion, mucoid or mucopurulent conjunctiva, with redness. The lids are glued together in the morning and the patient complains of burning and itching and a gritty feeling. There is no involvement of the cornea and the increased blood supply is confined to the first system of blood vessels—the posterior conjunctival. The congestion is greatest at the periphery and diminishes as it approaches the cornea, the vessels being easily emptied on pressure.

Just a word with reference to the blood vessels in the conjunctiva, a knowledge of which will enable the practitioner to distinguish at a glance between serious and benign inflammation involving the eyeball. There are three systems of blood vessels in the conjunctiva. The first, or posterior conjunctival system of blood vessels are always seen in health; they enter at the periphery and travel toward the corneoscleral margin; they are of a bright red velvety color and are easily compressible; they can be emptied by pressing the fingers over the closed lids; the congestion is more marked at the periphery and lessens as it approaches the cornea. Congestion of this system is indicative of a simple process and is usually accompanied by increased secretion. The anterior ciliaries, or second system of blood vessels, consist of the anterior ciliary perforating and non-perforating arteries and veins. They are not visible in health, except the perforating which in dark complexioned persons appear as small brown dots on the conjunctiva about five millimetres from the corneoscleral margin. When they are inflamed there is a brick red congestive band beginning about five millimetres from the corneoscleral margin which extends toward the periphery. The greatest congestion is near the cornea; they cannot be emptied on pressure. This is indicative of a severe inflammation of the eye such as iritis, cyclitis, or glaucoma. The third system is the anterior conjunctival, which are not seen in health and when inflamed extend into the cornea from the corneoscleral margin. They are not compressible and this is indicative of a severe process, such as keratitis phlyctenula.

In a case of conjunctivitis, if you wish to determine the cause accurately, make a smear on a microscopic slide and have it examined. The pneumococ-

cus is probably the germ most frequently found; streptococcus and diphtheria bacillus may be present. The Koch-Weeks bacillus is the cause of epidemic catarrhal conjunctivitis or pink eye.

Treatment.—Warm local applications of boric acid or normal saline are indicated. In the office the conjunctiva can be touched, with a solution of silver nitrate. If the case does not clear up promptly the patient should be sent to a specialist or eye dispensary for more exhaustive study.

Chronic catarrhal conjunctivitis.—There is little or no secretion. While it otherwise presents the picture of acute conjunctivitis, the lids may be much thickened. Sometimes it is confounded with trachoma but the presence of trachoma bodies, scars and atrophic areas makes the picture clear. Spring catarrh, or vernal conjunctivitis, is a condition which occurs in youth. Its appearance in the warm season, the elevations resembling cobble stone, and the film of bluish white secretion serve to differentiate it.

Gonorrhoeal ophthalmia.—Every general practitioner should be thoroughly conversant with the preventive and prophylactic measures used in ophthalmia neonatorum. Unless he sees the treatment carried out in a lying-in hospital or an eye dispensary, he is not competent to do anything except give first aid treatment. A year ago a baby was brought to my office after three weeks treatment for ophthalmia neonatorum by the family doctor, who then told the mother to wash the eyes with boric acid solution until the discharge stopped, as nothing further could be done and the baby would probably be blind. The Lord was with him, for the infection was of a mild type. Although there was a great swelling and profuse purulent secretion, the corneas were not involved. How they escaped I do not know. The child made a good recovery without loss of vision by strenuous and persistent treatment.

Hordeolum or sty.—Suppuration of the glands of Zeiss and Moll is called external hordeolum. They are single or multiple and are often recurrent. The treatment is quite simple. Hot applications in the form of a poultice or gauze pad dipped in hot water and the application of a salve composed of the yellow oxide of mercury gr. 1—petrolatum album drams 11, usually hastens the process and brings it to a head. The pus may be evacuated with a sharp scalpel, after which the salve is continued and the hot compresses omitted, until recovery takes place.

It is well to remember that hordeoli are frequently produced by eyestrain, even though the vision appears to be normal. Every physician should have in his office eye test cards, both for distance and for near vision, but must understand that the ability to read the finest print is no indication that there is no eye trouble. There may be low refractive errors which frequently produce a great variety of reflex nervous symptoms. Prescribing glasses may put an end to the trouble.

Chalazion—internal sty.—It is evident that there is a close relationship between a hordeolum and a chalazion as a chalazion is simply a blocked up meibomian gland, causing a tumor of the eyelid. The sac is filled with gelatinous or cheesy material. Occasionally it may go on to suppuration, usually point-

ing inward, and rupturing forms a granulating area on the under surface of the lids. Occasionally the orifice of the gland may open and the contents gradually be expelled; then in a few months it fills up again. There is no treatment of permanent value but excision. If this is not carefully done and the sac entirely removed, the trouble recurs. Salves, hot applications, and massage are of very little service. This condition, like hordeolum, is frequently caused by eyestrain.

Foreign bodies on the cornea.—These are of considerable importance and the practitioner will do well, in these times of workmen's compensation, to handle them with kid gloves. It is of the utmost importance that a correct history of the character of the injury be obtained and the size and location of the foreign body noted. The best way to record the location of a foreign body is to consider the cornea in the aspect of a clock face. The upper part is at twelve o'clock, the lower at six o'clock, and the intervening points approximate to the numbers on the dial. The distance of the foreign body from the centre of the cornea or from the corneoscleral margin is then noted. You record a foreign body on the cornea, for example, at six o'clock three millimetres in from the corneoscleral margin or the limbus, and you have its exact location for future reference. The size of the foreign body is also noted in millimetres. Many very small sharp foreign bodies may, because of the speed which they attain in flying through the air, upon striking the eyeball penetrate and hardly leave a mark at the point of entrance.

A case in point may be cited. A man was struck in the eye by a foreign body, but as far as could be seen there was no evidence of injury. He suffered pain and on very close examination, with oblique illumination, a faint gray pin point area was noticed on the cornea near the limbus at three o'clock. When a magnet was applied to this area the iris pulled toward it, showing that the foreign body was imbedded in the iris. Under cocaine anesthesia, a small incision was made at the point of entrance, the tip of the magnet applied, and a piece of steel less in size than a pin head was removed without any very great injury to the iris. The x ray did not show this minute piece of steel. More skill is required to remove foreign bodies from the cornea than in doing more serious operations.

In the past we saw many bad scars following corneal ulcerations and even lost eyes, because some workman was supposed to be specially clever in removing foreign bodies from the eye. All cases occurring in the shop were sent to him. Even now, under present conditions, I find that many company physicians, nurses, and many general practitioners are hardly more skillful. I presume they do not understand the technic, have not the proper instruments, and do not appreciate the danger of careless handling.

I usually instil four per cent. cocaine in the eye, put in a clean eye speculum, seat the patient with a bright light over his head, put on a head mirror, and throw a beam of light on the cornea. With a magnifying lens in one hand and a sterile eye spud in the other, the foreign body is gently removed.

Occasionally a few drops of sterile boric or saline solution are dropped into the eye and the area is wiped with a cotton tipped probe dipped in boric or saline solution. It is better not to attempt to remove all the rust stain from the bed on which the foreign body has rested. Nature will take care of this.

Prescribe a boric wash, and if the injury is extensive instil one drop of one per cent. atropine solution. Be sure to apply a sterile bandage; if you do not the eye may become infected and you are liable to suit. Instruct the patient to return the next day for observation; in this way the best results may be obtained.

Corneal ulcers, phlyctenular disease and keratitis.—These fall in the realm of the specialist. The general practitioner will get best results by not handling these cases, but there is no reason why he should not have charge of them, see them occasionally and take charge of their general treatment and dietetic regulation.

Pterygium.—This occurs in teamsters, builders, farmers and other workers exposed to air and dust. It is frequently due to exposure and to foreign bodies, as dust or sand, getting into the eye. I have never seen any good results from local treatment, although I know there are some men who are enthusiastic about the application of alcohol. Operation is the procedure of choice.

Every practitioner should at least know how to diagnose iritis and glaucoma and also how to prescribe the initial treatment, especially where the patient cannot get to a specialist promptly. I will give you the differential diagnosis between iritis and glaucoma and say a word about the immediate treatment, because in these conditions, unless we are alert, irreparable damage may be done.

DIFFERENTIAL DIAGNOSIS.

Acute Iritis.

Intense bright redness of bulbar conjunctiva, intense pericorneal infection.

Cornea clear, very sensitive. Anterior chamber normal or deep.

Pupil contracted immobile, synechia often present.

Iris discolored, markings obliterated.

No contraction of fields.

No cupping of disc. Usually no increase of tension.

Intense pain radiating to side of face.

Acute Glaucoma.

Rather dusky bluish redness of bulbar conjunctiva; rapidly failing vision.

Cornea steamy, anesthetic.

Anterior chamber very shallow.

Pupil dilated, immobile, greenish in appearance.

Iris markings present not discolored.

Contraction of fields. Rainbows seen around lights and flashes of light; disc cupped.

Tension greatly increased.

Sick stomach and vomiting often occur; violent pain coming on frequently at night.

IMMEDIATE TREATMENT.

Iritis.

Instil one or two drops of one per cent. solution of atropine three times a day or more often as occasion requires to dilate the pupil.

Hot compresses, leeching.

No operation.

In iritis unless immediate and strenuous treatment is begun early the eye is badly damaged, but in glaucoma, unless remedial measures are instituted at once to combat it, the eye is lost. Therefore, it behooves the general practitioner to familiarize himself with these two important conditions.

Patients with glaucoma will often prevent a good result by refusing operation and sometimes the ophthalmologist will assist in this, as in a case which I shall cite. A woman called in her family doctor for violent pain and a red eye. Thinking it was iritis he instilled atropine. The next morning the eye was worse, so he sent her to me. I immediately used eserine, hot compresses, leeching, and advised immediate iridectomy, which was refused. I took her to another ophthalmologist who advised the same operation, but it was refused, so I dropped the case. Then they went, as they said, to a good eye doctor who was going to cure her with medicine; later I learned that she went to a prominent oculist in Philadelphia who continued the eserine and saw her three times a week for three months at five dollars a visit. Result, a totally blind eye.

Here I wish to say a word about hot and cold compresses. Cold compresses are indicated for acute conditions and should be applied constantly and are of very little value after forty-eight hours. Hot compresses are of use in many cases from the beginning and can often follow cold compresses after forty-eight hours. They are usually applied from fifteen to thirty minutes every three hours or at longer intervals. It will pay every general practitioner to own an artificial leech, by which he can withdraw blood from any congested area. I am surprised to find that in many hospitals it is not available. Natural leeches are hard to get and are not nearly so satisfactory.

This paper would not be complete without calling your attention to a condition which means a great deal to the patient from a cosmetic and economic standpoint, namely, the recognition of the condition known as squint or strabismus and the proper method of handling it. Every physician should at least know that there is a fusion centre which enables us to fuse the images which fall on corresponding parts of the retinas, and the difference between a phoria, which is a tendency of the eyes to deviate from parallelism, and a tropia, which is an actual deviation or turning of the eyes from parallelism and

Glaucoma.

Instil one or two drops of solution eserine grain one-eighth to one-fourth to the dram three times a day, or more often as required to contract the pupil.

Hot compresses, leeching.

Operation in twenty-four hours unless tension decreases and symptoms subside.

is manifest to the most casual observer. To demonstrate a phoria have the patient look at an object in the distance with one eye while you cover the other eye with a card. Look behind the card and if the eye is not looking straight ahead, you have a phoria or latent squint. Remove the card and the eye will quickly return to its original position of parallelism. Many intractable eye conditions and reflex nervous symptoms are due to this anomaly.

MONOCULAR AND BINOCULAR VISION.

It has been said that one eye is a necessity, two eyes a luxury. Cross eyed persons can shoot accurately because they only use one eye in sighting; they can tell direction, but cannot measure distance so well. They cannot thread a needle or direct the hand to a small object accurately. Binocular vision measures distance and speed more accurately than monocular vision. The development of binocular vision is one of the most important epochs in a child's life. We watch their dentition. We look after their tonsils and adenoids and yet when a child is brought to us with a squinting eye, we physicians pass it up and tell the parents the child will grow out of it. Why? Because we often forget or do not know about fusion sense or fail to recognize the importance of binocular vision.

Every physician knows the approximate date of the coming of the first tooth and when a baby should walk and talk, but he fails to study the sight of the child. Every babe at birth has only light perception. In a few weeks it can recognize large objects; later small objects, and during this time one eye may wander out or in while the other eye is straight. This is not harmful in the first six months. When a child directs both eyes to the same object, it is beginning to acquire binocular vision. This it does in the second half of the first year. Five years or more are necessary to complete the establishment of binocular vision which lasts through life.

Remember, binocular vision begins in the first year and is completely established by the sixth or seventh year and cannot be acquired after the seventh year. If the squint develops during this time or double vision occurs, the child learns to suppress one image and becomes amblyopic or blind in the squinting eye. Therefore these cases should all be sent to the oculist for study, treatment or operation and many eyes will in this way be saved.

A knowledge of this special work and the ability at least to give intelligent advice in these eye cases will be of great service to the general practitioner, especially in these times of advanced knowledge and I think the patients have the right to demand it. I am sure it will not harm but will assist the specialist in getting better results as the proper treatment will have been started and no valuable time will be lost.

SOLUTIONS.

Atropine is used in eye work, mostly in solutions of four grains to the ounce; eserine solution, one grain or less to the ounce; argyrol, ten per cent. to twenty-five per cent.; nitrate of silver, one to four grains to ounce, and in some special cases as high as twenty grains to the ounce; cocaine, twenty grains to the ounce. Cocaine should not be used much in

ulceration of cornea, as it will dissolve the cement substance in the corneal tissue and cause maceration. Holocaine in about the same strength can be used instead of cocaine. Zinc sulphate, as an astringent, one grain to the ounce; saline (normal) salt solution and a saturated solution of boric acid are the usual collyria in simple forms of congestion. For quick results adrenaline 1 in 1,000 may be added, five minims to the ounce. Every man doing compensation work should have an ounce of fluorescein solution on hand to stain the cornea to determine breaks in its continuity. The following is the formula: Fluorescein eight grains; sodium bicarbonate, eight grains; distilled water, one ounce. One drop is placed on the cornea and it is immediately washed off with boric acid or saline solution. It will leave a greenish stain on the broken corneal surface, but will not stain healthy tissue.

2028 CHESTNUT STREET.

REPORT OF FIVE OPERATIVE EYE CASES.

By EDWIN B. MILLER, M. D.
Philadelphia,

Associate in Ophthalmology, Temple University; Assistant Professor of Ophthalmology; Graduate School, University of Pennsylvania; Ophthalmologist to Roosevelt Hospital, Philadelphia.

In looking over the journals from time to time, we find reports of many rare and interesting cases and interesting accounts of new operations. I am going to depart from this and report a few cases from the ordinary group in which there appeared interesting features requiring somewhat different technique in handling. The first three cases were due to known injuries, the fourth probably to unknown injury and the fifth due to a disturbance in metabolism which produces cataract—in this case probably glycosuria.

CASE I.—March 26, 1917. J. F. was admitted to the Roosevelt Hospital with the following history: While at work in a bottling establishment was struck in the right eye by a flying piece of glass from an exploding soda water bottle. Thirty minutes after the accident, his eye presented the following appearance: There was an irregular linear incised wound of the cornea extending from just below the limbus at 7 o'clock to the centre of the cornea and then up and out to the limbus at 11 o'clock; the anterior chamber was empty and the iris was prolapsed into the wound at the upper and lower margins.

Under cocaine anesthesia after cleansing the conjunctival sac, I cut off the iris at both places and replaced the cut edges, instilled atropine, applied ice compresses and kept the patient in bed for a week, when he left the hospital in good shape and one month later refraction showed the following result: Right eye $+2.50+2.00$ ax $75=20/70$; left eye $+.50$ ax $90=20/20$. He had vision in all directions, except up and out where there was quite an extensive leucoma. The interesting points in this case are the escape of the other structures of the eye from injury and the rapidity with which recovery took place. In all cases of this character, I now perform conjunctivokeratoplasty.

CASE II.—February 17, 1919. I. K., colored,

aged thirty-four, sustained an accident similar to that in the first case. While working in a bottling establishment he was struck in the right eye with a piece of flying glass from an exploding soda water bottle. An hour later I saw him at the Roosevelt Hospital and found the following condition: A wound of the cornea semilunar in shape extending from the limbus at 11 o'clock to just above the centre of the cornea, then up to the limbus at 2 o'clock. The anterior chamber was empty and the iris was prolapsed at 11 o'clock. Atropine was instilled and ice compresses were applied. Under cocaine anesthesia, I cut off the prolapsed iris, replaced the pillars, smoothed down the wound with a spatula and covered the entire area by a conjunctival flap. Five days later when the stitches had sloughed out and the conjunctiva had retracted, I noticed that the lens had become entirely opaque. There was no infection and on April 2nd, when the eye was entirely quiet, I evacuated the lens material with a keratome. He made a good recovery. When the eye was entirely quiet, I performed a V shaped capsulotomy and secured a large black pupil; with the correcting lens his vision was $20/30$ for distance and $.75$ D type for near. The refractive error in the left eye was corrected giving him $20/20$ distance and 37 D type for near. A plain glass was placed over the right eye.

The interesting point in this case was that the injury while very much less than in the preceding case, produced a rapidly forming traumatic cataract, there being probably a slight break in the anterior lens capsule.

CASE III.—J. B., aged sixty-five, March 7, 1919, was removing a tire when the wrench slipped, striking him in the left eye. I saw him at the Roosevelt Hospital several hours after the accident and the eye presented the following appearance: There was a slight abrasion on the forehead above the left eye, also a small cut below the lower lid; the cornea was uninjured, the anterior chamber was deep, the iris was badly torn at 6 o'clock and there was partial dislocation of the lens down and in; a small amount of blood was visible in the anterior chamber. Vision was $3/200$. His right eye had been injured in childhood; the pupil was irregular and about three millimetres in diameter. There were some remains of the lens capsule around the pupillary margins, the lens having been absorbed; the central area was clear. Vision was $1/200$.

This man was kept in bed for a week, atropine was instilled and ice compresses were applied. All the inflammatory symptoms promptly cleared up and on the fifteenth day the eye was quiet. On March 31st I removed the lens with some loss of vitreous. A few days later, there developed a slight infection at the lower outer corner of the wound. Under treatment this rapidly cleared up and some weeks later refraction showed, right eye $+9.00+1.00$ ax $180=20/30$; left eye $+11.00+2.50$ ax $165=20/20$. Add $+2.50$ for near= 50 D type. Before the accident he only had protective vision in the right eye, never having obtained a suitable glass. Now he has two good eyes for distance and close work.

The interesting features in this case were the absence of injury to the cornea in view of the severe

injury behind it, and the rapid clearing up of the vitreous cloud which was present during the slight infection.

CASE IV.—An Italian woman referred to me by Dr. M. E. Smukler presented phthisis bulbi in the right eye following injury in childhood and a mature cataractous lens in the left eye, which was partially dislocated into the anterior chamber, being tilted backward above. The patient had light perception and projection down, up and in. Under narco and cocaine anesthesia I made the usual corneal incision with a conjunctival flap and immediately the woman turned her eye up. Because of her ignorance, even with the aid of an interpreter, we could not induce her to roll the eye down, and therefore it was impossible to do an iridectomy. As the pupil was well dilated and the lens was tilted backward above, I decided to deliver the lens in its capsule. Using two Smith lid elevators, Dr. Smukler holding the lids well up and open, by the use of hook and spatula the lens was tumbled without difficulty and came out under the upper lid, without loss of vitreous or prolapse of the iris. The toilet of the wound was then made and the eye closed. On examination of the lens, we found it was a distinctly black cataract, Morgagnian in character with the capsule loosely attached, so that one could lift the capsule up from the lens with a forceps. The patient made an uneventful recovery and left the hospital in eight days. Unfortunately there was an old retinal detachment including a good part of the nasal side, thus explaining the absence of temporal light projection and changing what would have been a perfect result into a case of only useful protective vision. The interesting point in this case is the good clean simple extraction obtained in an illiterate unruly patient while working under difficulties.

CASE V.—Wm. A., aged seventy-nine, had mature lenticular cataract in both eyes, light perception and projection being good. The patient had an old chronic diabetes. Operation was refused by another oculist, because of his age and the amount of sugar present, but as he wanted to see and was willing to take a chance, I agreed to operate without promising him any result and told him of the danger. I thought it wise to do a preliminary iridectomy in his left eye to thoroughly test the advisability of an extraction. Under narco and cocaine anesthesia a small iridectomy was performed. This operation was a perfect success; there was prompt healing and hardly any reaction. Thus encouraged I attempted to extract the lens. Before my corneal incision was finished the zonule ruptured below and some fluid vitreous began to come out. When I attempted to rupture the capsule, the lens moved with the cystatome in all directions. I eventually got a fair opening but the lens was soft and sticky and when about half of the lens substance was expressed so much vitreous was lost that I decided to stop. Replacing the remaining capsule and lens and replacing the iris pillars I closed the wound. I should have covered the entire incision with a conjunctival flap.

The next day I took a look at the eye and it seemed all right although the entire pupillary area was filled with lens substance and capsule. When I paid my second visit I found that the wound had burst open

and the remaining lens and capsule was in the open wound. There also was leaking of the aqueous at the outer corner but after looking at it from every angle, I decided to leave it alone and take a chance. This I explained to the family. I watched it for fifteen days. No infection occurred. On the fifteenth day the anterior chamber closed, the lens absorbed rapidly down and out and there was a clear area 3x5 mm. through which I could see the faint disc outline. He has good protective vision; I held a +12.00 condensing lens before his eye and found he could read 1.50 D type. I intend to do a capsulotomy and hope to get a good result. The interesting features in this case are first, the corneal flap was sufficiently nourished even though two-thirds of it was cut off from its blood supply for at least ten days; second, there was no infection in spite of the fact that the anterior chamber remained unclosed above and no increase in tension occurred after the wound closed, even though there was considerable debris in the upper angle; third, the remarkable manner in which the wound healed in an old diabetic is worthy of note; fourth, of great interest is the useful vision obtained in spite of the loss of a large amount of vitreous.

There are numerous questions that arise as we survey a series of cases like this, but time will not permit of their full discussion. Reports of difficult cataract cases and how the operator meets the difficulties would be both interesting and instructive.

2028 CHESTNUT STREET.

EYE CONDITIONS OF INTEREST TO THE GENERAL PRACTITIONER.*

By LOUIS F. LOVE, M. D.,

Philadelphia,

Surgeon, Ophthalmological Department, St. Mary's and
Misericordia Hospitals.

The general practitioner is frequently called upon to diagnose and treat ailments of the visual organ that are either emergency cases or diseases of such minor importance as to make the services of the eye specialist unnecessary. It is apparent, therefore, that in order to institute proper treatment and achieve results he must have a thorough knowledge of the eye conditions most likely to come under his care and at least a general familiarity with the more serious ocular affections that he may encounter in the course of his practice. This paper aims to give to the busy physician, in succinct form, the information he may require in his work, and aid him in treating intelligently conditions that too often are neglected because of insufficient knowledge of the subject, particularly that pertaining to the differential diagnosis of the commoner eye affections.

CONJUNCTIVITIS.

Perhaps the most frequent condition encountered in general practice is conjunctivitis. The physician will be called upon to differentiate between a simple inflammation of the conjunctiva and a disease of the deeper structures of the eye, such as, for ex-

*Read before the Kensington Branch of the Philadelphia County Medical Society, November 7, 1919.

ample, iritis and glaucoma. In order to make a careful distinction between these conditions the practitioner should recall something of the structure of the visual organ. The conjunctiva or delicate membrane that lines the eyelids (palpebral conjunctiva) and covers the front of the globe (ocular conjunctiva) receives its blood supply from two sources—the posterior conjunctival and the anterior ciliary vessels. In marked inflammations of the anterior section of the eye both the ciliary and the conjunctival vessels are injected. As a rule, however, the differentiation between the two forms of injection is readily made. When the conjunctival vessels are injected there is clearly visible a superficially disposed vascular network that can be moved easily along with the conjunctiva. The diseased structures take on a vivid scarlet or brick red color. In ciliary injection the individual vessels cannot be clearly made out, and when the conjunctiva is displaced, the vessels do not move along with the membrane. The latter is an important point in differentiating an inflammation of the conjunctiva from diseases of the deeper structures of the eye, as for example, iritis and glaucoma. The redness is prone to be more diffuse than in conjunctival inflammations, and there is a rose red or pale violet zone about the cornea—circumcorneal injection.

In differentiating these diseases one from the other we have as valuable diagnostic aids the discoloration of the iris, the presence of which should be ascertained by careful comparison with the normal eye. In conjunctivitis the iris remains unaffected, whereas in iritis and in glaucoma the iris is discolored. The diagnosis is influenced also by the size of the pupil, which is contracted in iritis, dilated in glaucoma, and unaffected in conjunctivitis. In conjunctivitis there are pain and tenderness, but the pain is not neuralgic, as in iritis and glaucoma.

An inflammatory glaucoma is often mistaken for an iritis by the presence of ciliary injection and discoloration of the iris, symptoms common to both diseases, a mistake which is rendered doubly grave by the fact that although we use atropine freely in the treatment of iritis, we know that it must never be instilled in a glaucomatous eye. In glaucoma the injection is decidedly venous in character or dusky red in color; the episcleral veins are large and tortuous, owing to the pressure on the vasa vorticosa throwing greater work on the anterior ciliary veins. In iritis the injection is general and intense, especially circumcorneal injection of the ciliary vessels. In conjunctivitis the injection is velvety and increases away from the cornea and toward the fornix. In acute glaucoma a characteristic symptom is the loss of vision, frequently coming on suddenly and being out of all proportion to the apparent inflammatory condition; in iritis the loss of vision greatly depends on the cloudiness of the aqueous or the exudation in the pupillary space. In simple conjunctivitis the vision is unimpaired, depending on the photophobia or the amount of mucus or pus which may float over the cornea.

Diseases of the conjunctiva form, on an average, thirty per cent. of all eye affections; in epidemics, of course, this percentage is much higher. For gen-

eral clinical purposes conjunctivitis may be divided into three forms, the hyperemic (and congestive), the catarrhal, and the purulent. There are, however, many subdivisions, such as croupous, diphtheritic, traumatic, trachomatous and scrofulous, but in these forms the conjunctivitis is merely a symptom of a special exciting cause. In the majority of cases of acute conjunctivitis the morbid matter is brought into contact with the conjunctiva through the medium of the atmosphere; this has been proved in a form of conjunctivitis by the discovery of a special bacillus by Koch-Weeks, Morax-Axenfeld, Hansell, and others. But there are also instances in which a poisonous element, circulating in the blood, has been the cause of the conjunctivitis. In measles, before the rash appears upon the body, there is frequently observed a conjunctivitis, this constituting, therefore, a prominent symptom of a beginning rubeola.

The prognosis of acute catarrhal conjunctivitis is favorable in uncomplicated cases, the disease disappearing spontaneously in from eight to fourteen days. The complications that arise in conjunctival catarrh consist for the most part of corneal ulcers. The onset of these complications is manifested by an increase in the pain and heightened photophobia. These complications are often the result of attempts at treatment of the catarrh by the laity, who do not hesitate to apply bread and milk poultices, tea leaves, raw meat, urine, or even a bit of placenta. The transmission of the secretion from one individual to another plays an important part in spreading the disease; for this reason the indiscriminate use of towels, handkerchiefs, and the like should be carefully guarded against. Search should always be made for foreign bodies, for atoms of dirt or dust may have become lodged in the cornea or in the conjunctiva of the upper lid. Indeed, a conjunctivitis is frequently brought on by a foreign body creating a condition that may give entrance to an infective germ; a type of this form frequently seen is the so-called pink eye.

The treatment of acute conjunctival catarrh is very simple: Frequent flushings of the conjunctival sac with a saturated solution of boric acid, with a little cocaine or sulphate of zinc combined, anointing the edges of the lids with borated petrolatum to prevent agglutination, and the instillation of a few drops of a solution of one of the silver salts, such as a twenty per cent. solution of argyrol, repeated at intervals. Applications of a solution of nitrate of silver, about one grain to the ounce, to the upper and lower lids once daily should also be used if necessary. The patient should be instructed to avoid dust, smoke, and vitiated air in general, and pass as much of his time as possible in the open air. At the onset a purge should always be administered. Stimulants, as a rule, should be avoided. The nasopharynx should be carefully looked after, and refractive errors corrected. The use of atropine cannot be too strongly condemned. In a simple conjunctivitis the drug is useless, and in some cases may, indeed, do much harm.—It should never be used unless there are decided indications for its employment.

OPHTHALMIA NEONATORUM.

All authorities are now agreed that ophthalmia neonatorum is due to but one cause, and that is infection. Statistics also show that the disease is an easily preventable one, and one that is readily cured if recognized in time. It is with the general practitioner that the early diagnosis of this disease rests, for it is on prompt treatment in the early stages that the preservation of sight depends. The disease is readily recognized, for all physicians are familiar with the congested eyes, the swollen conjunctivæ, the overlapping lids, from which thick pus exudes, and the dim and embedded cornea.

For the prevention of this disease the Credé method should be universally adopted. In fact a national law, instead of depending on certain States for the adoption of such a law, should be passed compelling every physician, midwife, and nurse to use a drop of one or two per cent. solution of silver nitrate in the infant's eyes as soon as possible after birth. In fact I am convinced that the invariable employment of the Credé method would almost entirely eliminate ophthalmia neonatorum and its dreadful consequences. It is reasonably certain that at the present time there is no remedy that can take the place of nitrate of silver, either in the prevention of this disease or its treatment.

In a recent communication to the different health boards of the large cities of the United States, it was astonishing to find the wide diversity of opinion and legislation in the different cities regarding the prevention of blindness in the newborn; but in the cities where the free distribution of nitrate of silver was made to the midwives and nurses, cases of ophthalmia neonatorum had been reduced considerably. The superintendent of the Philadelphia Lying-in Hospital says that in her eight years' experience in that institution she has never seen a patient who was harmed or injured by the instillation of silver nitrate, and this experience has been repeated again and again in many lying-in institutions. It has been stated that one fifth of all the blind asylums in the United States could be eliminated if the Credé method were universally adopted by obstetricians, nurses and midwives.

ETIOLOGY.

It is now generally conceded that ophthalmia of the newborn is acquired in the great majority of cases by the infection of the eyes of the infant with the vaginal secretions of the mother during the passage of the child along the birth canal. A few cases of antepartum infection have been found, and infants have been born with bennorrhæa fully developed, or the cornea already destroyed, but these cases are extremely rare, only 105 I believe, having been reported up to the present time.

In a large majority of cases the gonococcus has been found present in the pus from the affected eyes. Streptococci, staphylococci, pneumococci, and other pathogenic organisms have been detected microscopically, but when these have been the cause of the infection, the malady with proper treatment has usually run a mild course and gone on to ultimate recovery. When, however, infection by the gonococcus takes place, the course of the disease is usu-

ally a virulent one and may progress until sight is destroyed.

Sidney Stephenson, in his valuable essay on ophthalmia neonatorum, sums up the four main factors in the etiology of the disease. He says: 1. That a majority of mothers of ophthalmic babies are affected with vaginal discharge at the time of delivery. 2. That in most of these cases gonococci could be found not only in the pus from the maternal passages, but also in pus from the inflamed eyes. 3. That microorganisms other than the gonococcus could occasionally be demonstrated in the nongonococcal forms of ophthalmia. 4. That the serious cases of ophthalmia, that is, such as were likely to impair the sight, were almost invariably due to the specific microbe of Neisser. Neisser found the gonococcus present in 68.47 per cent. of ninety-two cases of ophthalmia, and in a total of 1,658 cases reported by forty-one observers gonococci were demonstrated in 67.14 per cent.

It has been shown and confirmed by numerous investigators that most pregnant women suffer from catarrh of the vagina, with a mucous or purulent discharge, and hence are in a condition to infect the eyes of their babies. While this is so, it must be remembered that gonorrhæa is often a latent disease, and that acute symptoms may be absent or remain quiescent. It is well known that pregnancy, labor, and the puerperal state are likely to cause a recrudescence of an old Neisserian infection, and the chronicity of this disease has been demonstrated by the fact that the gonococci have shown renewed activity after lying dormant in the genital tract for years. All this goes to show that the genital discharges of seemingly healthy women may convey infection to the eyes of the newborn, and thus the innocent offspring be deprived of their most valuable faculty.

The indications in the treatment consist of: 1, the employment of agents known to have a destructive effect on the gonococci; 2, the use of antiseptic or cleansing washes to keep the eyes free from infective matter. For the former indications the eyes should be carefully washed with a boric acid solution and a two per cent. silver nitrate solution applied to the surface of the everted lids by means of a cotton probe. Both lids should be carefully gone over quickly and thoroughly, paying particular attention to the little folds in the conjunctiva. The eyes should be subsequently washed at frequent intervals with a boric acid solution.

Let me emphasize that the treatment, to be effective, must be prompt. The second application of the silver solution should follow in from eight to twelve hours after the first. Too much stress cannot be laid on the necessity for keeping the eyes free from pus accumulations. This can only be accomplished by repeated washings, at fifteen minute intervals if necessary, both night and day, using a boric acid solution, as previously directed, or potassium permanganate or solution of bichloride of mercury, although mercury solution may prove irritating. In order to secure the most complete attention, it is generally necessary to use two nurses, one for night duty and the other for day. Too much stress cannot be laid on the necessity for

observing the strictest asepsis regarding everything coming in contact with the child. The newer silver salts, argyrol and protargol, in my opinion, possess certain advantages and should be used in conjunction with nitrate of silver but under no circumstances should the nitrate of silver be omitted.

KERATITIS ECZEMATOSA, PHLYCTENULAR KERATITIS,
OR PHLYCTENULAR CONJUNCTIVITIS.

This condition is characterized by the formation of single or numerous vesicles (phlyctenules) on some portion of the cornea or conjunctiva, and is accompanied by photophobia and blepharospasm. It is seen in scrofulous subjects—most frequently in children before the age of puberty, and less often in adults. It occurs in connection with inflammatory diseases of the nasal passages and adenoid vegetations. "The affection often follows measles or other acute exanthemata."

The phlyctenules appear upon the cornea, usually at or near the corneoscleral junction. At first gray, they rapidly break down, forming the phlyctenular ulcer, with vessels running to it. Their appearance is accompanied by an exacerbation of all symptoms. When the ulcer heals, the blood vessels disappear, but a strip of opacity remains. A microscopic examination of the epithelium of the affected areas reveals the presence of microorganisms—*Staphylococcus pyogenes aureus* and *albus*.

The treatment of simple phlyctenular keratitis consists of instilling atropine in sufficient strength to maintain dilatation of the pupil, thus putting the eye at perfect rest, and allaying inflammation. Hot stupes are useful in relieving pain and in promoting healing. Good hygiene should be maintained and sanitary surroundings looked into. Local cleanliness should be assured by the free use of boric acid solution. Diet and outdoor exercise are important factors. Of drugs, yellow mercuric oxide ointment may be used, and when the inflammatory conditions are subsiding, dusting the eye with calomel is a useful procedure. Codliver oil, iron, quinine, minute doses of calomel, and arsenic should be prescribed to meet the individual constitutional requirements. Refractive errors should be corrected

IRITIS.

In inflammations of the iris the symptoms depend largely upon the degree of hyperemia and the character and location of the exudate. Hyperemia of the iris is not, properly speaking, a disease, but merely a symptom, and it is only when the hyperemia becomes so extreme that an exudate is formed that a true inflammation—an iritis—can be said to exist. In iritis the acuity of vision is diminished in proportion to the amount of effusion and accompanying cloudiness of the aqueous or the exudate in the pupillary space. If the pupil is occluded, the eye is, for the time being, almost totally blind.

Among other symptoms must be mentioned, first, the pain. This is, as a rule, very characteristic. It begins as a dull, deep seated pain, as if the eyeball were being pressed upon. This increases in severity as the inflammation progresses, and is accompanied by sharp twinges, usually along the course of the fifth nerve. Thus it is that supraorbital neuralgia is a conspicuous symptom. Paroxysms of intense pain occur, gradually increasing in severity and

number as night approaches. This pain is different from that due to any inflammation external to the eye, and is throbbing and stabbing in character.

Another important symptom in iritis is the change in the color of the iris, in addition to the loss of its natural lustre. This is due to hyperemia, which causes a normally blue or gray iris to appear greenish—a change particularly marked when comparison is made with the unaffected eye.

Iritis may, in certain cases, resemble glaucoma, but the severity of the symptoms will easily differentiate it from simple conjunctivitis. The physician may, however, occasionally be misled by symptoms common to many inflammations of the deeper tissues, such as photophobia and injection of the conjunctiva. Yet of all inflammations of the eye iritis is that most readily recognized. The iris is at first discolored and contracted, and its power of movement impaired. The pupil loses its glossy blackness, there is a deep ciliary injection, and the cornea is dull. When the disease has progressed to the formation of an exudate and the iris has apparently become fixed, the nature of the disease can positively be diagnosed.

Rheumatic or gouty iritis occurs most commonly in middle life, and may be present along with other rheumatic affections. In rheumatic or gouty iritis the treatment should be directed toward relieving the pain and maintaining mydriasis. The customary treatment of rheumatism and gout should also be prescribed.

In my opinion gonorrhoea is a frequent cause of iritis and we can usually obtain a history of gonorrhoea when we fail absolutely to get one of lues. It is well, therefore, in suspected cases, in the males, at least, to examine the urethra and urine. Generally however, the history of gonorrhoea is not of recent date. In the majority of cases the suspicion that syphilis is the cause of iritis is well founded. In the secondary or tertiary stage of syphilis a form of iritis is occasionally seen, evidenced by the inflamed iris and the presence of yellowish or reddish brown nodules—gummata or condylomata—situated generally at the pupillary border. A Wassermann should always be made.

The treatment consists essentially of the free exhibition of mercury, perhaps salvarsan, local sedatives, and as in other forms of iritis, atropine freely. Dilatation of the pupil should be maintained until all irritation has subsided. Local measures to relieve the pain and congestion, such as Swedish leeches or the heurteloup to the temple, are useful, as are hot water fomentations applied at frequent intervals, and dionin also may be used.

GLAUCOMA

We shall now consider that most serious of eye diseases, glaucoma, a name applied to several varieties of a disease of which increased intraocular tension and dilated pupil are likely to be the most prominent symptoms. The tension of the eye may be estimated by palpating the eyeball through the closed lids with the index fingers, just as when testing for fluctuation in any other part of the body. It should be done with deliberation and care. A tonometer may be used.

In making a diagnosis of glaucoma the sound eye should always be used for purposes of comparison. Under normal conditions the intraocular pressure is quite constant, but in morbid conditions considerable variations occur. It should be remembered that the eyeballs of elderly persons are generally harder than those of the young. The early recognition of glaucoma by the general practitioner is of the greatest importance, for in this disease, more than in any other, prompt and proper treatment may save an eye that a mistaken diagnosis or improper treatment would invariably destroy. Inflammatory glaucoma is frequently mistaken for iritis, and as a consequence, is treated with atropine—which has a most disastrous effect upon a glaucomatous eye.

Glaucoma as an idiopathic disease usually attacks those of fifty or over, although younger persons are not immune. During the early stages the conjunctiva is seen to be hyperemic, the cornea slightly smoky and anesthetic, the aqueous cloudy, and the pupil moderately dilated. The association of inflammation and dilatation is seen in no other disease of the eye, while the peculiar sombre redness of the inflammation has its own significance. In glaucoma vision is usually much worse than in iritis—except in iritis with occluded pupil. The patient complains that he does not see well—as if a cloud of smoke were obscuring things. If there is a light in the room, it may be encircled by a halo of rainbow hues. If the physician examines the eye during the attack, he finds the cornea somewhat dull, anesthetic, and diffusely clouded, resembling ground glass. After such an attack which usually lasts several hours, the eye may assume an apparently normal condition. As the disease progresses these attacks become frequent, and the patient complains of pain in the head, ears, and even in the teeth. The pain is, in fact, intolerable. An examination at this time shows all the evidences of a violent inflammation—edema of the lids and of the conjunctiva, the latter being greatly congested. The injection, being preeminently of a venous character, is of a dusky red color. The cornea is dotted and presents an appearance of smoky cloudiness. It is almost or quite insensitive to the touch. These are the symptoms of an acute attack. In the third stage the eye is completely blind. Vomiting frequently occurs, a symptom that has often led to errors in diagnosis, the patient being treated for gastric disturbances, while the ocular symptoms were regarded as neuralgia or conjunctivitis.

Every case of glaucoma if allowed to go untreated will probably end in complete and incurable blindness, and the necessity for an early recognition is thus at once made apparent.

Treatment should be directed toward the reduction of tension. For the relief of pain and in the hope of curing the disease iridectomy or trephining is without an equal. Morphine hypodermically is invaluable, as likewise is eserine. The coal tar products are also useful. When all is said, however, early operation is the treatment. Mental depression must be overcome. Glaucoma cannot be cured, but in favorable cases acute attacks may be cut short by pilocarpine or eserine.

THE HISTORY OF ACIDOSIS.*

By WILLIAM HENRY DONNELLY, M. D.,
Brooklyn, N. Y., .

Instructor in Pediatrics in the New York Postgraduate Medical School and Hospital; Chief of Children's Nutrition Clinic, Brooklyn Hospital.

While the subject of acidosis as we now know it is of comparatively recent development, an investigation of the literature on the subject shows that it had its origin seventy years ago. The term acidosis was first used by Naunyn (1) in 1906, and was applied by him to an abnormal metabolic condition in which hydroxybutyric acid was formed. The broader use of the term has been the rule since the writings of Henderson in 1909, Sallards in 1914, Peabody in 1914, and Howland and Marriott in 1916.

The theory of acidosis had its inception in 1850 when a French investigator named Boussingault (2) made the discovery that large amounts of ammonia frequently appeared in the urine of advanced diabetic patients. Modern writers frequently ascribe this discovery to a German observer named Hallervorden (3), who in 1880 repeated and confirmed Boussingault's work, and so stated in his writings. The reason for this is evidently the highly unfavorable criticism of Boussingault's German contemporaries as to his methods and technic. However, Schaffer (4) has shown that Boussingault's technic was distinctly superior to that of all of his contemporaries. In the meantime A. Kussmaul (5) in 1874 made the first clinical observation in noting the dyspnea in advanced diabetic patients which he named air hunger. His description was classical, describing the expansion of the thorax in all directions, the following of complete inspiration by complete expiration, with absence of cyanosis, and of congestion of the veins of the neck.

In 1883 E. Stadelmann (6), in the search for acid radicals to account for the presence of ammonium salts in the urine, discovered betaoxybutyric acid. In this paper he set forth the acid intoxication theory and indicated the logical alkali therapy as it is used at the present day. In the same year Von Jaksch published a paper (7) describing the substance which gave Gerhardt's ferric chloride test in diabetic urine, and positively identified it as acetoacetic or diacetic acid. He included diacetic acid in his acetone theory of diabetic coma, having proved definitely while working in his father's laboratory that the volatile substance obtained from the distillation of fever and diabetic urine is acetone. Soon, however, acetone was proved to be negligible in its toxic effects, and Von Jaksch was unable to substantiate his contention that acetone was the mother substance of the other so-called acetone bodies.

On the other hand, Walter (8) in 1877 had demonstrated that mineral acids were capable of combining with basic groups in the blood, and that ingestion of these acids by animals proved fatal, although the blood serum remained faintly alkaline to litmus. Magnus-Levy (9) in 1899 showed that the chief alkali robber in dyspneic coma was beta-

*Read before the Brooklyn Pediatric Society, April 28, 1920.

oxybutyric acid. Knoop of Strassburg (10), in the opinion of Folin made in 1905 the most important advance since Stadelmann, namely, demonstrating that fatty acids are the main source of supply of the acetone bodies. Folin (11) states that these fatty acids which contain an even number and not less than four carbon atoms can be oxidized to oxybutyric acid.

Walter had found a uniformity of symptoms in the administration of hydrochloric acid to rabbits. If the quantity inserted into the rabbit's stomach exceeded .9 gram to the kilo of body weight, death came within a few hours. The phenomena were ushered in by increased frequency of respiration, each respiratory movement being more labored, deeper and accompanied by forcible heaving of the body walls. The animal lost the power of motion and lay in one position. Fifteen minutes after this stage was reached the dyspnea ceased, blood pressure fell, the heart action weakened and stopped, although respiration ended before the heart ceased to beat entirely.

Up to this period in the literature nothing had been done on the carbon dioxide tension either of the blood or of the alveolar air. Haldane and Priestley (12) in 1905 devised a method of getting alveolar air by means of a three quarter inch hose with a glass mouth piece. Lindhard (13) in 1911 reported a method of getting the alveolar air by a Krogh glass valve with a small flexible lead tube with an interior bore of one mm. which was passed as far as comfortable into the pharynx. Then Plesch (14) in 1909 suggested the rebreathing of a limited amount of air until it was in equilibrium with the air in the alveoli.

In 1914 Peabody and Boothby (15) working in the Peter Bent Brigham Hospital in Boston evolved an apparatus with a three way valve by which the patient breathed into a bag for a given length of time. They filled the bag with 1,000 c. c. of air so as to allow of a deep inspiration on the part of the patient. Their apparatus was a modification of one described by Porges (16) and they agree with him that the optimum time of breathing into the bag is twenty-five seconds, and the average carbon dioxide tension is about forty-five mm.

Howland and Marriott (17) warn us that acetonuria and acidosis are not synonymous terms. The acetonuria of starvation or increased food requirement rarely results in acidosis. Acidosis probably depends on the same underlying cause as most cases of cyclic vomiting. Marriott (18) in 1916 brought out a colorimeter of standard phosphate solution colored with phenolsulphonphthalein. This was primarily meant for use in children and the child was made to breathe into a bag twenty-eight to thirty-two seconds, avoiding collapse of the bag, and then the air was passed through a test solution colored in the same way as the standard tubes and then compared with them. The colorimeter tubes are arranged in series with a ground glass background and are calculated so as to give at once the carbon dioxide index in the same way as a hemoglobinometer. With this test set the normal carbon dioxide tension in the adult is shown to be forty to forty-five mm.; in children three to five mm.

lower. A tension of thirty to thirty-five shows a mild degree of acidosis, one of twenty imminent danger, while in coma with acidosis it may be as low as eight to ten mm.

The first adaptation of a clinical method of estimating the carbon dioxide given off from the blood plasma or the carbon dioxide tension of the blood was reported by Van Slyke in 1915 (19). He found that the results attained were the same as those with the alveolar air methods and this has been repeatedly verified since that time.

The prophylaxis of acidosis in intestinal conditions in children is advised by Schloss (20) using in severe cases the veins or longitudinal sinus with a four per cent. bicarbonate of soda solution, or a two per cent. solution subcutaneously. In March, 1920, in a lecture before the Harvey Society at the New York Academy of Medicine, Marriott expressed his belief in the causation of acidosis by the anhydremia produced by the loss of body fluids in diarrhea, and stated that he had found the most rapid and efficacious method of combating the acidosis in intraperitoneal injections of normal saline which promptly corrected the dehydration of the blood.

CYCLIC VOMITING.

While there is a definite and serious difference of opinion among pediatric observers as to the connection between cyclic or recurrent vomiting and acidosis, it must inevitably be considered in any history or investigation of acidosis.

It seems that the first important description of the disease was by Gruere (21) in France in 1838-1841. Marfan (22) in 1905 and other French writers have associated recurrent vomiting with acetonemia, and have even called it acetonemic vomiting, on the ground that acetone is so constantly present in the urine. There is no evidence, as Marfan admits, that acetonemia produces the attack, since acetonuria is seen in so many other affections. D. L. Edsall (23) in 1903 pointed out that the presence of betaoxybutyric acid indicated the possibility of the condition being an acidosis, and advised full doses of sodium bicarbonate even in the intervals. Griffith (26) thinks this has much in its favor, but is wanting in certain proofs, and the difference between acetonuria and acidosis is to be borne in mind, as was pointed out by Howland and Marriott (17) in 1916. Mellanby (24) in 1911 and Sedgwick (25) in 1912 found a urinary secretion of creatin at the time of the attack, and believed that this was due to abnormal metabolic changes. Sedgwick also thinks that adenoids are a powerful etiological factor. Richardière (27) in 1905 believed that the occasional coexistence of icterus was an evidence of the involvement of the liver in the disease process. Charles Hunter Dunn (28) is so convinced of the connection between this condition and acidosis, that he divides the latter subject into recurrent vomiting and acid intoxication.

CHILD HEALTH WORK IN THE SOLVAY SCHOOLS.

By GEORGE M. RETAN, M. D.,
Syracuse, N. Y.,

Instructor in Pediatrics, College of Medicine, Syracuse University.

The objects sought in our health work in the Solvay schools are threefold: First, to lower mortality rate; second, to prevent sickness, and third, to encourage the best possible mental and physical development in each individual child. The work is divided into four general heads: 1, the prenatal clinic; 2, the infant welfare clinic; 3, the preschool clinic which fills the gap between the age of infancy and the school age, and 4, the school welfare work which takes the child from kindergarten through high school.

The conditions at Solvay have been unusually favorable for the success of this plan. Solvay is an incorporated village of 6,000 inhabitants. It has fifty-one per cent. of foreign population. The village is a suburb of the city of Syracuse. It has its own water supply and sewerage plant. Practically all of the streets are paved. The school system con-

sists of a high school, two graded schools and one rural school. There are 1,588 pupils. There are no hospitals but we have access to the wards of the Syracuse hospitals and to the free dispensary connected with Syracuse University.

The entire work is under the supervision of the school physician. The staff consists of the school physician, an ophthalmologist, a dentist, a dental assistant, two school nurses, one baby welfare nurse, a visiting housekeeper, a nutrition worker, and a physician who conducts the prenatal clinic. The prenatal clinic is held each week. We have at present ten women registered. This clinic is held by Dr. Clara Gregory assisted by our baby welfare nurse. A maternity history is taken and physical examination including pelvimetry is made. Urine and blood pressure examinations are made each month during the early part of pregnancy. This is done every two weeks during the later months of pregnancy. The doctor advises the expectant mother regarding her diet and mode of living. The teeth are filled and a mouth wash prescribed. The women are encouraged to go to the hospital for their confinement.

The infant welfare work is divided into two general headings, work in the clinics and field work. It is done in cooperation with the State Child Welfare Department. The clinics are held each Monday afternoon. At these clinics any mother in the town is allowed to bring her infant. From September 1, 1918, to September 1, 1919, we cared for 522 babies. The general form in each new case is filled out by the nurse and any additional facts suggested are added by the physician. The babies are weighed at each visit by the nurse and a weight record made. The chief purpose of this clinic is to teach mothers to feed their babies properly. Every attempt is made to induce mothers to nurse their infants. In spite of our efforts we find that thirty-one per cent. of the babies are bottle fed. This percentage should be much lower and we are making the greatest effort to bring it down. This high percentage is in part due to the mothers and in part due to the family physicians. Many mothers seem anxious to take their babies from their breast for insufficient reasons and doctors often advise this without careful investigation. Breast fed babies may have digestive disturbances when the breast milk is normal. These disorders are due to irregularities in the intervals of feeding, to the manner of living on the part of the mother and to insufficient length of single feedings. It should be the duty of the attending physician to insist that the mother nurse her baby at stated intervals and also that she nurse the baby for a definite number of minutes as the conditions warrant. Further than this the mother should be instructed in regard to the manner of her living and hygiene during this period.

The problems of infant feeding form a large proportion of the problems presented in infant welfare work. We insist that our babies shall be fed with certified milk. The bacterial counts of all milk used are obtained at least once a month. For a year we supplied a certified cow's milk at a reduced cost to mothers who were using bottle feed-

ings. The milk was distributed directly from the school at a cost of nine cents a quart. At that time grade A milk was selling for eleven cents a quart. We did this in order to demonstrate to them the superiority of certified milk for infant feeding. We feel that this demonstration was a success for since we have stopped distributing milk we have no trouble in inducing mothers to use the best grade of milk. I think that it is important for the physician in charge of an infant welfare station to keep himself informed regarding the bacterial counts of all milk used by the mothers. In private pediatric practice infant feeding presents a different problem than in a baby welfare clinic. A pediatricist has many difficult feeding cases to care for, while in the welfare clinics the large proportion of patients are normal babies and are not difficult to feed. We use dilutions of whole milk basing the amount on the caloric requirements. Cane sugar is used in most cases. I am convinced that it is not necessary to ask mothers to buy the more expensive sugars used in infant feedings. In our feeding both breast and bottle babies we insist that our infants be fed at a regular stated interval and I feel that we are successful in getting the mothers to do this.

After instructing the mothers regarding the new formula, the nurse is sent to the home to show the mother how the formula should be made up, the proper care of the milk and how to cleanse and care for nursing bottles and nipples. The home visits of the nurse are of vital importance in conducting a baby welfare clinic. Without this work the clinic could not succeed. Our nurse makes a visit each month to the town registrar for a list of the births and infant deaths during the preceding month. The nurse calls at the home to interest the mothers in the welfare clinic and asks them to bring the babies to the clinic for examination. The list of infant deaths is used by the physician in his attempt to lessen cases of preventable sickness. The nurse is instructed to advise that the family physician be summoned to care for any sick infant who, in her opinion, requires medical aid. This is of advantage since many cases are thus placed under a physician's care earlier than would otherwise be true. The nurse continually advises mothers in matters of cleanliness, diet, in the care of milk and in the care of nursing bottles and nipples.

Cases of respiratory diseases are often seen at the clinic and if these are of a benign nature remedies are prescribed. I feel that this is better than allowing the mother to use household or drug store remedies as these cases would rarely be taken to a physician for treatment. No attempt is made to treat the more serious diseases as bronchitis or pneumonia. The mothers are always instructed to discontinue all feedings and give the baby plain water or barley water. If the nurse considers the case of any possible serious nature the family physician is summoned at once. The early treatment of intestinal diseases especially in the summer months is of the first importance and we feel that by stopping the feedings and by placing the case early in the hands of a physician, the high mortality rate can be materially diminished.

Another idea that we have developed and which we feel is of distinct advantage is the manner in which our clinics are held. The patients are seen and examined by the doctor in the same room and in the midst of the mothers who are waiting and each point explained to the mother is also heard by those mothers waiting. All mothers, in this way, receive repeatedly the principles of infant care and hygiene. The annoyance caused by the infants and children in the room is offset when mothers see these principles successfully applied. I believe that this is the reason that we are able to have practically all of the babies fed at regular intervals.

The infant mortality in Solvay has steadily decreased since the clinic has been in operation. Last year we had enrolled in our clinic seventy per cent. of the infants in the village. This year that percentage has been increased. The mortality rate for 1916 was 156. For 1917 the mortality rate was ninety-seven. For 1918 it was eighty-three. The infant welfare clinic in its present form was organized in 1917. Before that time we were holding clinics but without a nurse who devoted all of her time to the work. I believe that in order for a baby welfare clinic to be successful it is necessary for the physician to be paid. One of the first requisites of a successful clinic is the regular and prompt attendance of the physician in charge. Since most physicians gain their livelihood through the recompense they receive from their private practice, it is necessary for them to respond to their calls and consequently they are often late to the clinics or are not able to attend. If they receive sufficient compensation for the work the clinic could demand their prompt attendance.

The preschool clinic cares for children between the ages of two and five years. From the viewpoint of preventive medicine this is an extremely important period. It is the period during which the child forms faulty food habits. Many children who have been properly fed during the first two years of life are allowed to select their own diet during this period. Many children begin at these ages to eat whatever diet their fancy dictates. Faulty food habits once formed are extremely difficult to change. This is also the age in which many children learn to drink coffee and to eat candy before meals. These habits sadly affect their nutrition and their resistance to infection. If the nutrition is decreased seven per cent. below the normal their rate of growth is retarded. The teeth during this period should receive attention. Carious teeth should be filled since the decay and early loss of the primary set affects the development and formation of the jaw.

This is also the period during which the adenoids should be removed. The changes in the face, the retarded development of the nose, the high arched palate, the flat chest and the middle ear complication produced by adenoid growths could largely be prevented if the adenoids could be removed before the age of five. All children attending school receive at least one physical examination a year. This includes an examination of the height, weight, nutrition, eyes, ears, nose, teeth, throat, glands, heart

and lungs. All children are examined with the chest exposed.

The routine examination is made in the following manner. The height and weight are taken. The mouth is inspected, examining the pharynx first, then the teeth. The hands are now passed along the sternomastoid muscle to determine the condition of these glands and along the back of the neck for the same purpose. The heart is then examined oscillating each of the four valvular areas. Examination of the lungs consists of at least six oscillations in front and the same number in the back. The forced cough at the end of expiration is used in making examinations. The chest is also examined for D'Espine's sign. By these methods efforts are being made to detect the early stages of tuberculosis. This examination is made in an average of three minutes. Without using the forced cough at the end of expiration and the D'Espine sign the examination can be made in an average of two minutes. If school children are to be examined at all and a careful examination can be made in this time I see no reason why it should not be done.

I believe that there is a close relationship between the work of the school physician and the prevention of tuberculosis among children. Until more exact methods of diagnosing early cases have been worked out, I feel that we can accomplish much in the way of prevention by applying our present knowledge. During my first year in Solvay I found children with pulmonary tuberculosis, who showed positive signs and tubercle bacilli were found in the sputum. The conditions in a school room with children closely associated for five hours each day are ideal for continuous infection. For these reasons I believe that it is not safe for children to attend public schools in which children are allowed who do not have their chests examined at least once a year. Further than this I believe that many cases of tuberculosis among children could be prevented were this universally done.

I have thought that we could go farther and find the earlier cases and with this idea in view we are making a list of the children who come in contact in their homes with known patients with tuberculosis. Patients who show suspicious physical signs are listed and reexamined and if these signs persist on the second and third examination we will attempt to have an x ray taken and an examination made by a specialist.

The nutrition of each child is measured by a scale (1) which I have prepared which divides nutrition into four classes: 1, overnutrition; 2, excellent nutrition; 3, passable nutrition; 4, malnutrition. The observations made each year are placed on a separate chart for each child and these observations connected by a line form a curve of the child's nutrition during school period. If a child is found to be malnourished he is placed in one of our malnutrition classes where an effort is made to correct his nutrition.

The principal causes of malnutrition may be classified as: Physical defects, 1, adenoids, 2, hypertrophied tonsils; 3, decayed teeth; 4, eyestrain; habits, 1, food habits, coffee, tea and alcohol and candy

between meals; 2, lack of rest; hygiene, 1, sleeping in congested, unventilated rooms; disease, 1, any actual diseased condition as tuberculosis or syphilis.

During the past year an attempt was made to correct our malnutrition cases after the plan of Dr. Emerson of Boston. A special nutrition worker was engaged who was trained by Dr. Emerson. This year we have divided the malnutrition cases into two sections. One section is cared for by this nutrition worker after the plan of Dr. Emerson, the other section is in charge of our dietitian who is a graduate of Mechanics Institute at Rochester. The majority of all malnutrition cases are either caused by infected tonsils and adenoids or by faulty diet and often a combination of the two.

The result of tonsillectomy on nutrition is shown by the following data. This gives a summary of the weights of ninety-five children who have had their tonsils removed for at least a year. These children have lived under the same conditions following tonsillectomy and have received the same diet. Six pounds was used as an average yearly gain for a basis of comparison. Sixty-eight patients or seventy-one per cent. gained more than six pounds. Three children failed to gain during the year and two cases lost weight. One of the two children that lost weight had active pulmonary tuberculosis.

We have made an investigation to determine the diet of 530 school children between the ages of five and twelve years. The diets were separated into three classes.

This data showed that nearly half of our children receive insufficient food and that over half of these children are in the habit of drinking coffee. You can see the importance of considering diet in relation to any nutrition problem.

No child is allowed in either class whose malnutrition is obviously due to any physical defect as adenoids, tonsils, etc. The Emerson system as practised by our nutrition worker mainly works through the child. The interest of the child is obtained in his own physical growth. He is asked to fill out a note book showing the amount and character of the food he eats. His diet is corrected and the approximate number of calories he consumes each day is placed on the chart each week. He is asked to take a daily extra lunch and if he does so a red star is placed on the chart each week. He is also requested to take a rest period each day. If this is done a blue star is added. A weight curve is kept showing the progress in weight. The chart also shows his normal weight curve. When he has reached the normal curve he is graduated. He is also asked to give up drinking coffee and requested to slip with the windows open nights. The classes of malnutrition are held once every week. In these classes the nutrition worker teaches the children what food is for, the kinds of food that are best suited for growth, the harm done by drinking coffee and tea and matters of hygiene. The case of each child is then considered separately. In the event the child has gained the reasons for this are brought forward and the child is encouraged. In case he has not gained the reason for this lack of gain is

sought and he is stimulated to greater efforts. The physician regularly visits the class and adds his influence toward gaining the cooperation of the child. Food models are used to aid in teaching the children a balanced diet and food values.

The dietitian conducts her work by using the class method of teaching the children diet and hygiene and by visiting the home and teaching mothers proper methods of cooking and preparing food, what foods to buy to keep within their income. She advises the parents to allow the children to drink no coffee and to sleep with windows open. She also uses extra rest periods for the badly nourished. The results of these two experiments will be of interest.

The following list gives the defects found from September 1, 1918, to June 30, 1919:

Defects		Treated
Vision	149	149
Hearing	14	11
Teeth	510	508
Nasal breath	160	92
Tonsils	273	138
Nutrition	215	130
Cardiac	16	16
Pulmonary	12	12
Nervous	13	13
Orthopedic	13	13
Skin disease	151	151

Through the operation of the Boyd School Dental Clinic, this condition has been practically eradicated. A summary of the work done in the dispensary from February 15, 1917, to April 8, 1919, is as follows:

Treatments	1,329
Extractions	1,895
Cement fillings	920
Amalgam fillings	2,890
Silicate cement F.	254
Cleanings	1,255
Extractions	1,017
Total	9,560

The value of this work estimated at the rates charged in dental offices is \$10,242. The fees paid by the patients were \$455.15. The actual cost of equipment and salaries was \$5,679. The value of the work to the community is apparent. The community, realizing the value of this work, has this year assumed the expense of the dental department.

We are now carrying on a plan of preventive dentistry. After a molar tooth has become decayed many treatments are needed before this tooth can be filled. If the dentist could fill this tooth when the carious process first begins, much time would be saved the dentist, and many extractions would be prevented. Under a plan of preventive dentistry a large proportion of the 1895 extractions which we were forced to do could be prevented and very little treatment work would be needed.

The success of preventive dentistry can be shown by the fact that from February, 1917, when the dental clinic began to August, 1918, including the first seventeen months of its operation, we treated on an average of eleven, six year molar teeth each month. From September, 1918, to June, 1919, a period of nine months, we treated on an average of four, six molar teeth each month. And from September, 1919, to December, 1919, the past four

months, we treated on an average of but 2.4 each month. The six year molar is the first permanent tooth and as you will remember we found twenty-five per cent. of the children with these teeth so nearly decayed that they required treatment before filling. If we could work only on our own children and those who enter school at kindergarten ages, we could entirely eliminate this tooth destruction, but we will always have some children with badly decayed molars who come to us from other schools.

We have been unusually successful in correcting errors of refraction. In 149 cases found the last school year we corrected one hundred per cent. Much credit is also due the nurses in the follow up work. They did not rest content until these children were provided with proper glasses. After glasses have been provided it is necessary to see that they are worn.

The enlarged tonsils and adenoids present a difficult problem to the school physician. We have been extremely cautious in selecting cases in which we advise operation. Our opinion has not always been substantiated by the family physician. Unfortunately there is some difference of opinion among the doctors in regard to what kind of tonsils should be operated. I feel that doctors should consider a case carefully before giving advice. From our 273 cases we were able to have 138 operated, which is fifty per cent.

In concluding I want to correct an impression that I have heard advanced many times regarding this work at Solvay. I hear that this manner of work is not practical since we have unlimited funds of money at our disposal. One would think that at Solvay resided a Midas with a golden touch. This is not true. We can spend money only when we can show that the expenditure will bring sufficient results to warrant it. Every dollar spent must show at least a dollar's worth of results. It is purely a business proposition and we are spending no more money than any community ought to spend in proportion to its population. If the conservation of children is of importance, money must be spent to put methods of conservation into successful operation. It cannot be done in any other way. Compare the expense of child education with the expense of child welfare work. We are spending but one dollar for health to every eighteen dollars spent for education. It is not sound business to spend large sums to educate a poorly nourished child with adenoids, enlarged tonsils, flat chest, retarded physically one or more years. Figure the loss of time and money in attempting to teach a child to read whose eyes will allow him to see the printed page but imperfectly. And shall we allow our educators to spend their time on a child with tuberculosis, not to mention the other children he will start along the same highway to chronic diseases?

None of this work described costs too much for any community if we expect to train a future generation of virile, healthy, energetic men and women.

REPORT OF A CASE OF MELANOMA.*

*From Gouverneur Hospital, N. Y., Medical Service.*By S. R. MONTEITH, M. D.,
New York.

There are three features of the case under consideration which lead us to report it: First, the volcanic rapidity of its clinical course; secondly, the distribution of the metastases as shown at autopsy, and the comparatively minute quantity of pigment seen in the tumor masses.

CASE.—Patient, M. K., an adult white female aged twenty-three years, admitted to the wards of Gouverneur Hospital, October 25, 1919, at 8:40 a. m. The patient while thin and undernourished did not evidence a marked degree of cachexia. She was markedly dyspneic, somewhat cyanotic and jaundiced. The jaundice, while marked, was of a lemon yellow tint but not bright yellow. On the right back, at the lower part of the neck, above the scapula, was a large firm reddish cauliflower mass, raised above the surface of the skin three-eighths of an inch and measuring one and a half inches transversely by an inch vertically. This mass was sloughing, and from it exuded a bloody discharge. Extending outward from this mass was a scar which reached the shoulder. In the line of this scar, and attached to the skin, were two firm hard masses. There were other masses palpable; these will be described later.

The following history was obtained: The family history was negative for chronic diseases. The previous history was negative for any disease except measles in childhood. In reference to the masses described, they were first noticed by the patient five years previously, but gave her no concern. She had been in good health until four weeks prior to admission to the hospital. At that time the hard masses on the right shoulder began to itch; later, they ached and pained her. About a week after the beginning of this trouble (three weeks before admission to the hospital) her doctor had incised the most painful of the masses. From this wound the cauliflower mass had grown. It was fiery red in color, bled easily, and appeared to be bubbling over on top of the skin. The next symptom noticed by the patient was a severe, nonproductive cough; next, pain in the right upper abdomen. Later there were chills and fever, the cough became productive of a thick tenacious sputum, and a few days before admission the patient began to suffer from attacks of severe dyspnea.

In addition to these masses, there were other nodules as follows: Over the right side of the back, just within the inner border of the scapula, was a firm mass in the subcutaneous tissue, not attached to the skin, about one half by one quarter inch in extent. Over the left side of the back, on a level of the ninth dorsal vertebra, was a firm swelling not attached to the skin, but which seemed to be attached to the ribs for about three quarters of an inch. Over the right side of the neck posteriorly, on a level with the sixth cervical vertebra, and adjacent to the cauliflow-

er mass, was a nodule one half inch long. This mass was present in the subcutaneous tissue, but not adherent to the skin. Below this area and somewhat to the right was another similar nodule but smaller in extent. Posteriorly, in line with the posterior cervical lymph nodes was felt a large, firm mass resembling in consistency a large lymph node. This also was not attached to the skin. Here also, there were a few very small lymph nodes. In the left supraclavicular region there was a large nodule. The axillary lymph nodes were not palpable. The inguinal lymph nodes were not palpable. It is well, in view of the fact that there was no postmortem examination of the cranium, to emphasize the fact that no neurological disturbance was noted; the eyes seemed normal in reaction and in movement. There was no history nor evidence of ocular disturbance.

The heart was normal in size and position, the action was rapid with a harsh systolic murmur heard at the apex and transmitted to the axilla.

In view of the postmortem findings I wish to call especial attention to the lung signs: Motion was impaired more on the left side than on the right. Percussion showed flatness below the clavicle on the right lung anteriorly; auscultation gave low pitched tubular breathing, amphoric in character, over the same area with no râles present. Posteriorly, percussion and auscultation were negative. Over the left lung anteriorly there was flatness to percussion, and on auscultation low pitched tubular breathing below the clavicle. On inspiration there were many loud leathery râles. Posteriorly, there was complete flatness to percussion over the upper half of the lung. Auscultation gave, over the same area, marked tubular breathing, bronchophony, and coarse râles on inspiration and expiration. The left lung, clinically, was more markedly involved than the right lung.

In the abdomen the liver was palpable an inch below the costal margin. In the gallbladder area there was a round, hard mass, palpable over the liver just below the costal margin. This mass was the size of an egg and moved with expiration and inspiration. The uterus was palpable; the fundus being felt just below the umbilicus. Vaginal examination showed that the cervix was soft, the external os admitted one finger, the internal os being closed. There was no uterine bleeding.

Other features of the physical examination, including the reflexes, were negative.

THE CLINICAL COURSE.

On admission the patient had a temperature of 99° F., pulse 140, respiration 44. The cyanosis and dyspnea continued, and became progressively more marked. There were frequent stools, those of the first day being brown in color. On the following day the stools were clay colored and sticky. A small amount of urine was passed, not over 400 c. c. in twenty-four hours. This urine was of a dark amber color and smoky. Tests for albumin and glucose were negative. Microscopical examinations showed an occasional granular cast, with a few pus cells and erythrocytes. The blood examination showed erythrocytes 4,750,000; leucocytes, 23,500; eighty-five per cent. polynu-

*Read before Section in Medicine, New York Academy of Medicine, February 17, 1920.

clears; twelve per cent. small mononuclears; three per cent. large mononuclears; hemoglobin seventy per cent. (Sahli).

Suspecting the possibility of a melanotic tumor, the test for melanin was applied to the urine and was positive. This excretion of pigment, which is one of the many interesting features of melanotic tumors, is brought about as follows: By the metabolic processes of its chromatophore cells the tumor produces an excess of melanin. This pigment enters the blood. It is excreted by the kidney glomeruli as pigment granules; or as others hold the melanin in the blood is changed by the liver to colorless melanogen, which is in turn excreted by the kidney. The test used to determine the presence of melanogen in the urine, to quote from Wells, is as follows: "True melanogen may be considered to be present in the urine. First, if the careful addition of ferric chloride causes the development of a black precipitate. Secondly, if this precipitate dissolves in sodium carbonate forming a black solution. Thirdly, if from this solution mineral acids precipitate a black or brownish black powder. All three of these reactions must be followed out for there are substances other than melanin which will give the first two reactions." As you will see from the specimens presented urine containing melanogen will in time turn deep brown or black through the action of the oxygen of the air or other oxidizing agents.

Within a few hours after admission, the patient's respirations had increased to sixty a minute, and the pulse rate to 160. She became progressively weaker and finally died at 2.10 a. m., October 27th, having been in the hospital forty hours.

Autopsy was performed in the afternoon of October 27th by Dr. Schwartz of the Gouverneur staff. Interest in the autopsy centres largely around the distribution of the metastatic processes. I shall quote largely from the autopsy protocol. The first general autopsy incision revealed the liver slightly enlarged, extending a finger's breadth below the costal margin. The gallbladder was distended and extended about three inches below the ribs. The peritoneal cavity was free from fluid; omentum adherent to the lower part of the right side of the uterus and the pelvis. The pleural sacs were practically obliterated, apparently by adhesion. The pericardial sac was distended and contained over an ounce of clear yellow fluid. The heart valves were normal.

Over the left ventricle and projecting from the surface were four firm masses about three eighths of an inch in extent, which on section were raised above the cut surface, grayish white in color, homogeneous, firm and well circumscribed. One nodule extended through almost the entire thickness of the left ventricle. The anterior mediastinal lymph nodes were the seat of a metastasis. The right lung was separated with great difficulty from the chest wall on account of the infiltration of the costal pleura and intercostal muscles with tumor growth. The right lung was lumpy in consistency, and projecting beyond the pleural surface and into the substance of the lung were numerous large, well circumscribed, oval tumor masses; these were

grayish white in color, firm, and homogeneous, some being three inches in diameter. The left lung showed similar processes, but to a lesser degree. However, in the centre of the tumor mass of the left lung were two blackish circumscribed nodules about three eighths of an inch in extent. Let me emphasize this, for these were the only ones of the enormous number of tumor masses which showed any black pigmentation macroscopically. There was a large tumor mass in the vault of the diaphragm.

The pancreas was hard, nodular, and was the seat of extensive tumor growth, only a small portion of the gland remaining uninvolved. The liver was normal in size; surface smooth and on section was slightly softened in consistency, and of a brownish color, studded with red markings throughout. There were no macroscopic metastases to the liver.

The gallbladder was distended and contained black bile. Its mucous membrane and that of the ducts were normal. The spleen was normal, there were no metastases. Thus there were two organs commonly the seat of secondary tumor growth in this case apparently uninvolved. The right adrenal gland was much enlarged and the centre contained a large tumor mass, grayish white in color, about two inches in width. This mass was soft and easily disintegrated. The left adrenal gland was normal.

The kidneys were normal in form and size, and contained numerous circumscribed grayish nodules; capsule stripped easily, surface smooth with the exception of the areas where the tumor masses projected beyond the surface. The peritoneal coat of the bladder contained several small growths. The bladder itself was normal. The uterus was much enlarged measuring ten inches in length, seven and a half inches in width and three and a half inches in thickness. It contained a fetus of about six months and a placenta. It might be of passing interest to mention that the test for melanin applied to the amniotic fluid was negative. The right ovary was enlarged and contained a tumor mass two inches in diameter which completely obscured any ovarian tissue; left ovary and both tubes were normal.

There was a firm tumor at the cardiac end of the stomach an inch in diameter. This was ulcerated through, and over it the mucous membrane was absent.

The mesentery contained numerous nodules of varying size and of the same grayish white homogeneous material. The retroperitoneal lymph nodes were enlarged and numerous; on section they were pink in color.

The large tumor mass on the back was incised and was found to be surrounded by, and to lodge entirely in muscle tissue. In the muscle of the lower right chest wall there were two small firm grayish areas about one half inch in diameter. There was also an extensive infiltration of the intercostal muscles as described previously.

Permission to open the cranium could not be secured, thus valuable information as to the possible seat of the original tumor or of extensions to the central nervous system could not be obtained.

SUMMARY.

Here is a young woman who carried a tumor growth five years, without subjective symptoms. Then some event which we can only conjecture applied the torch. Within four weeks from her first discomfort, she is brought into the hospital so acutely ill that the diagnosis on admission was pneumonia. The picture presented was not unlike many seen in fatal pneumonia: cyanosis, jaundice, rapid pulse, and extreme dyspnea. Considering the colossal lung changes can we wonder at these symptoms?

In reference to the distribution of the tumor masses: The absence of macroscopical change in liver and spleen was striking. Interesting features are the degree of involvement of the heart, pancreas and right adrenal. And the findings in the muscles were rather unusual.

The lack of pigmentation also is a point worthy of note. Only one of the tumor masses, that in the left lung, showed black deposits to the naked eye or under the microscope.

NEPHRITIS.

BY HYMAN I. GOLDSTEIN, M. D.,
Camden, N. J.

During the past eleven years I have met with many interesting cases of nephritis—especially those occurring in children and young adults following slight and severe infections, such as tonsillitis, appendicitis, and other affections. In calling attention to this type of kidney disturbance, I shall also include a general review of renal disease as ordinarily found in the every day practice of the internist.

It is much easier to gain a general understanding of nephritis and its complications by having in mind some simple classification of the various types of renal disease. Many classifications have been put forward—based on clinical, pathological, chemical and etiological factors. Such classifications, after all, must necessarily lead to a more thorough study and analysis of cases and the result is a better understanding of renal conditions as they are presented to the internist.

Before reporting some of my own cases, I will mention some of the classifications of kidney disease.

Christian prefers to classify nephritis according to renal function as: 1. Patients with hypertension without definite cardiac or renal insufficiency—primary or essential hypertension (hyperpiesia). In some of these cases albuminuria and cylinduria are only occasionally present. 2. Patients with hypertension with renal insufficiency—most of these cases in later stages show cardiac insufficiency—cardiorenal cases in the later stages. 3. Patients with renal insufficiency with or without hypertension—the latter when present having developed secondarily to the renal insufficiency—chronic nephritis with or without hypertension.

In group 1 considerable edema does not occur; in group 2 edema is frequently met with and when present is usually of cardiac origin, though it may be of combined cardiac and renal origin. In group

3 considerable edema occurs, but is not frequently met with; when it occurs it is of renal origin. In the cases where hypertension is present, signs of chronic myocarditis usually appear later until myocardial insufficiency becomes an important factor. Edema with fair renal function is almost always of cardiac origin (these cases respond to digitalis promptly); on the other hand, edema with poor renal function is usually of renal origin (these cases do not respond to digitalis or diuretics). Christian does not approve of the use of the terms interstitial, parenchymatous or glomerular nephritis.

It is bold and one hesitates to suggest that we try to diminish the use of the name of Guy's Hospital's famous physician, but the term Bright's disease is not a good one. It has no set meaning and is a bad term to use to tell a patient his trouble—to many this gives a hopeless prognosis and life of short duration is predicted, and is as bad a term as rheumatism.

Riesman classifies nephritis as: 1. Parenchymatous—a, acute; b, subacute; c, chronic nephrosis. 2. Tubuloglomerular nephritis—a, acute; b, subacute; c, chronic (the chronic tubuloglomerular type being the old chronic interstitial nephritis. 3. The arteriosclerotic kidney.

Stengel's classification is: 1. Acute; a, mild tubular; b, severe tubular; c, glomerular, always severe. 2. Chronic—a, tubular, mild; b, glomerular, severe; c, renal sclerosis or arteriosclerotic kidney (senile kidney).

Stengel's acute mild tubular nephritis is due to infections, etc. There is no severe renal (functional) disturbance, no kidney symptoms, no elevation of blood pressure. The urine may show some albumin and some casts; the specific gravity is constant. In the severe tubular form, there is considerable dropsy, no elevation of blood pressure, no blood changes. In the acute glomerular type, the disease is always severe, there is high blood pressure, and marked nitrogen retention in the blood.

The chronic tubular cases are nearly always mild, and go on for many years, the patients are of an alabaster white complexion, have no marked elevation of blood pressure and no marked nitrogen retention in the blood (no other marked blood changes). There is some albumin and casts; dropsy is present; no marked renal inadequacy present.

The chronic glomerular type presents an altogether different picture; these cases are usually severe; this is the most severe type we meet with. The urine is of a high specific gravity; albumin and casts may or may not be present; there is early nitrogen retention in the blood; there is marked renal insufficiency, and a markedly low phenolsulphonephthalein excretion. These patients die in uremia, and live only one or two years.

The renal sclerosis cases are even more mild, and even more so than the chronic tubular—without danger to health and may go on for many years (senile kidney). The patients are arteriosclerotic; renal tests show more functional activity; blood nitrogen retention is not great. The blood pressure is high, because these cases occur in elderly people with arteriosclerosis.

Fischer states that there is really only one type

of nephritis—parenchymatous nephritis. He calls them generalized and focal nephritis, primarily and secondarily contracted kidneys.

Aschoff divides nephritis into acute inflammations: 1, chronic inflammatory nephropathies; 2, chronic degenerative nephropathies, and, 3, chronic circulatory nephropathies.

Volhard and Fahr classify the nephritides as follows: 1. Nephrosis (degenerative)—a, acute; b, chronic; c, terminal contracted kidney; 2, nephritis (inflammatory)—A, diffuse glomerular nephritis; a, acute, b, chronic, c, terminal; B, focal nephritis—a, focal glomerular; b, acute interstitial; c, embolic; 3, arteriosclerotic kidney—a, pure arteriosclerotic (benign hypertension); b, combination form (malignant hypertension).

Senator's classification is practical and most familiar to the profession: 1. Acute nephritis; 2, chronic nephritis; A, chronic parenchymatous; B, chronic interstitial; a, primary chronic interstitial nephritis; b, secondary chronic interstitial nephritis; c, arteriosclerotic kidney; 3, diffuse nephritis—a combination of parenchymatous and interstitial.

Widal suggested three groups of renal cases: 1, salt retention; 2, nitrogen retention, and, 3, mixed salt and nitrogen retention cases. The combined type is more common than the simple salt or nitrogen retention cases. The pure salt retention type of nephritis show only edema. There is an entire absence of serious symptoms and signs such as twitchings, coma, convulsions, Cheynes-Stokes breathing, marked hypertension (200 mm., or over, of mercury, systolic), acidosis (Kussmahl breathing), retinitis, anemia, hardened arteries, enlarged heart, loss of weight. Any severe symptoms as these with or without edema represent nitrogen retention type of nephritis. Frequent weighing of an edematous patient gives us a guide as to the retention or excretion of fluids in the study of these cases.

The general symptoms and diagnosis of nephritis need not be dwelt upon in this paper—they are well known and described in detail in all textbooks of medicine. To make a careful study of a case of nephritis, one must know the functional capacity of the kidneys and the various tests proposed. All of these help to make a decision as to the proper treatment and the indication or contraindication to the use of drugs.

As mentioned, weighing an edematous patient (if the condition warrants this with safety) is of considerable help as a guide as to retention or excretion of fluids; the study of salt excretion; tests for acidosis; study of the excretion of nitrogen waste products by chemical examination of the blood for urea. Study of the amount of phenolsulphonephthalein output and finally studies of the concentrating ability of the kidneys over a twenty-four hour period by the so-called renal test meal will show whether there is a true hyposthenuria (constant low specific gravity), and whether the kidneys can excrete concentrated urine with normal amounts of solids or not.

If renal function as measured by our functional tests is poor and the patient's condition indicates no serious disturbance in any other organ than the

kidneys, the probability of any great improvement in renal function is slight, except in cases of acute nephritis. Where the phenolsulphonephthalein test can be done, it is of service for the general practitioner. In the mild cases the phthalein excretion is normal or slightly depressed. In mild cases, too, blood urea N is normal or almost normal in value (unless the patient is on a high proteid diet) and therefore offers much help. It serves as a check on the phthalein test. The McLean or Ambard coefficient index in such cases is sometimes normal—often, however, this helps in making a prognosis. In the mild cases the two hour test is particularly useful, and in these cases if phthalein excretion is normal, the patient is placed on a diet containing seventy-five grams of protein and four grams of salt for two days and on the third day special meals—Mosenthal or Christian—the Frothingham or Schlayer and Hedinger diets are given, and the urinary collections of the two hour test are made.

A patient showing an excretion of thirty-five to forty-five per cent. phthalein is classed as a moderate renal case. Many of these cases, however, have cardiac disturbances with edema. In this type of case, in addition to the phthalein test, the renal function can be further learned by the administration of a diuretic such as agurin, theocin or theophyllin, diuretin or theophorin and if the edema improves with prompt diuresis, renal function is good, if not, renal function is poor and the prognosis is not so good.

Patients with less than thirty-five per cent. phthalein excretion have poor renal function and if patients do not have any cardiac disturbances, it usually means a severe kidney disease and offers a poor prognosis. Properly used tests of renal function are an aid in the treatment and management of renal cases and help in giving a more nearly accurate prognosis.

Thus, where the blood urea nitrogen continues to rise, we may be reasonably certain and so inform the relatives of the patient, that uremia is impending. Normally, the blood contains about twenty per cent. total solids; total nitrogen three per cent.; sugar .012 per cent.; chlorides as sodium chloride .65 per cent. and cholesterol .15 per cent.; nonprotein nitrogen twenty-five to thirty mgms. to the one hundred c. c. of blood; urea nitrogen twelve to fifteen mgms.; uric acid one to three mgms., creatinine one to two and a half mgms., creatine five to ten mgms. to the one hundred c. c. of blood.

In chronic nephritis the blood may show thirty to eighty mgms. nonprotein nitrogen and fifteen to fifty mgms. to the one hundred c. c. blood of urea nitrogen; in uremic nephritis you may get 120 to 350 mgm. nonprotein n, and eighty to 300 mgm. urea n, to the one hundred c. c. of blood—in these absolutely fatal cases you may have five, ten or fifteen mgms. uric acid per one hundred c. c. and creatinine up to thirty mgm. or more in one hundred c. c. of blood.

Myers and Lough and Gradwohl contend that the presence of over five mgms. of creatinine in one hundred c. c. of blood indicates an absolutely fatal prognosis. Blood chemical tests will help in differentiating so called cardiovascular disease from cases

of primary renal disease with secondary cardiac disturbance and lack of compensation. Blood tests in cardiovascular disease show practically no retention of nitrogen waste products, whereas nephritics with failing hearts show nitrogen retention.

Another point to be emphasized is that even in bad cases of nephritis urinary findings may be negative or scant so far as albumin and casts are concerned, yet an undue accumulation of urea *n*, uric acid, and creatinine will be found in the blood, and therefore the chemical blood work becomes at once a valuable method of estimation for true kidney function. Uric acid is the most difficult of all three (urea *n*, uric acid, and creatinine) for the kidneys to get rid of, urea next, and creatinine is eliminated with the least difficulty by the kidneys. Therefore, the staircase effect of Myers and Chase, emphasized by Gradwohl and others, is easily understood; first, uric acid is retained in early chronic nephritis, next as the case advances, urea *n* is retained, and finally creatinine. The uric acid retention occurs early in chronic interstitial nephritis, this is similar to the uric acid retention which occurs in gout. The urea is estimated by the Marshall method, the uric acid by the Folin method. (The Hellige colorimeter is used in all cases by Gradwohl). The Duboscq colorimeter is used by others.

The blood for these tests should be collected before breakfast, similar to the manner in which blood is taken for the Wassermann reaction. Potassium oxalate solution or a few crystals of the oxalate are put in the tube and the blood is well shaken. Amylase (amylolytic action) of urine is reduced in nephritis.

Uric acid is the first of the nitrogenous substances to be retained in interstitial nephritis.

Since gout and very early interstitial nephritis are characterized by essentially the same blood picture, it is necessary to employ every possible test to exclude nephritis before a high blood uric acid may be regarded as evidence of gout in the absence of the classical clinical manifestations.

Mosenthal and Lewis place considerable importance on the Ambard coefficient of urea excretion in their comparison of this method and the renal test meal with the Geraghty and Rowntree functional kidney test by means of subcutaneous injection of phenolsulphonephthalein. Others, while they admit that there seems to be something advantageous in this estimation of the ratio between the amount of urea in the blood and the amount of rate or urea excretion in the urine, quote the conclusions of Addis and Watanabe, that the rate of urea excretion in man varies under physiological conditions in a manner that cannot be explained by the concentration of urea in the blood and urine. The normal Ambard coefficient is .08; however, with the Dorémus ureameter, Gradwohl finds this test to be unreliable. McLean and Selling, with the Marshall method of urea *N*, estimation, have worked out another coefficient, which is more exact (the index of 100 is normal for McLean's coefficient).

Folin and Denis, Fritz and Frothingham showed (in experimental uranium nephritis in rabbits) that the retention of the nonprotein nitrogenous blood

constituents represented the difference between the quantity eliminated and the amount produced, whereas the Geraghty-Rowntree phenolsulphonephthalein test served as an indicator of elimination alone. Therefore, the blood chemical examination (for urea nonprotein) is the most valuable of all renal tests. The amount of nonprotein and urea in the blood is a measure of accumulating difference between the waste produced in metabolism and the amount eliminated by the kidneys.

ACIDOSIS.

By Van Slyke's estimation of the combining power of the blood plasma for carbon dioxide we may find exactly how much carbon dioxide a patient's blood plasma may take up and in that way determine the onset of uremic (nephritic) or diabetic acidosis. Normally, in the state of relative alkalinity of blood plasma, about sixty-five per cent. of the carbon dioxide will be taken up. As the acid bodies form which are part of the chemical changes seen in the blood acidosis, the blood loses this power to combine with carbon dioxide so that when the figure of fifty or less is reached, the patient is in danger of impending acidosis. This is more important than the finding of acetone, diacetic acid, or other constituents in the blood. The plasmas of normal adults contain from fifty-five to seventy-eight volumes per cent. of combined carbon dioxide as determined by Van Slyke's method. As stated, the bicarbonate content of the plasma is determined by measuring the carbon dioxide given off after the addition of an excess of acid. In the determination of the bicarbonate reserve of the plasma, it is found that in infants the normal values average about ten per cent. lower than in adults. Figures lower than fifty in adults and forty-five in infants are indicative of acidosis. The results if multiplied by seven tenths approximate alveolar carbon dioxide tension in millimetres determined according to the Marriott method (Van Slyke).

The determination of the carbon dioxide tension in the alveolar air (Marriott's method) may be carried out at the bedside. In normal children at rest, the carbon dioxide tension in the alveolar air varies from forty to forty-five. Tensions of between thirty and thirty-five millimetres are indicative of a mild degree of acidosis. When the tension is as low as twenty millimetres, the patient is in imminent danger. In coma, with acidosis, the tension may be as low as eight or ten millimetres. In infants the tension of carbon dioxide is from three to five millimetres lower than in older children or adults.

SELLARD'S ALKALI TOLERANCE TEST.

When the bicarbonate content of the plasma is within normal limits, the administration of a small amount of sodium bicarbonate by mouth raises the amount in the blood and brings about an alteration of the reaction of the urine. The excess of bicarbonate is excreted and the normally acid urine becomes amphoteric or alkaline. When there is acidosis, the bicarbonate of the plasma and of all of the body tissues is diminished. This must be replenished before bicarbonate by mouth will be excreted by the kidney. Therefore, the amount of

sodium bicarbonate that must be given to produce an amphoteric or alkaline urine is a measure of the depletion of the bicarbonate reserve of the body. With infants two or three grams of sodium bicarbonate is sufficient to cause an alkaline reaction of the urine; with older children and adults five grams are required. When acidosis is present much larger amounts of soda are necessary to bring about this change—sometimes five or ten times as much may be required. I take this opportunity to include these tests for acidosis, because we may have acidosis of renal origin.

The ability of the kidneys to excrete acid, especially acid phosphate, is one of the chief defensive mechanisms of the body—and failure of this mechanism leads to acidosis. In nephritis, when acidosis is present, there is an accumulation of unexcreted phosphate in the blood plasma. In these cases of acidosis, hyperpnea is present, the carbon dioxide tension in the alveoli is lower than normal, the alkali reserve of the blood is depleted and there is an increased alkali tolerance. No acetone bodies are detected in the urine and the ammonia nitrogen excretion in normal or diminished in cases of the acidosis of nephritis.

W. W. Palmer and L. J. Henderson have shown that nephritis commonly involves a state of acidosis. They conclude that the urinary concentration of ionized hydrogen is increased in the various forms of nephritis; and that acidosis is frequently present in renal cases—because when alkali (sodium bicarbonate) is administered it is in these cases retained by a kidney capable of the rapid elimination of an excess of alkali.

Marriott and Howland have shown that acidosis occurs in nephritis and the kidneys fail to excrete acid, especially acid phosphates, and they found an accumulation of unexcreted phosphate in the blood plasma. Henderson and Palmer have also shown that in every case of nephritis in which the condition of diminished ammonia excretion was detected, there has been a real retention of alkali. This is also commonly the case in other types of nephritis, even with heightened ammonia excretion.

Other methods used in the study of acidosis are the Marriott method for the determination of the hydrogen ion concentration of the blood or the indicator dialysis method for the determination of reserve alkali and the Barcroft and Peters quantitative method for the detection of acidosis—this latter test has for its basis the fact that the combining power of hemoglobin for oxygen is dependent upon the reaction of the blood. In acidosis the combining power is regularly diminished.

The Fredericia Plesch method may be used for the determination of the carbon dioxide in alveolar air.

Sellards' serum test consists in the precipitation of the proteins of one c.c. of serum by twenty-five c. c. of neutral absolute alcohol. The mixture is shaken and filtered through a dry acid-free filter paper. To the filtrate a drop of phenolphthalein solution is added and the fluid is evaporated to dryness on a water bath. Normally, a deep reddish purple color develops. In severe acidosis, there is a faint pink color or no color at all, but the addition

of a drop of water brings out a red color. In extreme acidosis the residue is colorless and remains colorless on adding water.

In acidosis due to an overproduction of acetone bodies, acetone, oxybutyric and acetoacetic acid appear in the urine in sufficient amount to be detected by qualitative tests.

But these are not enough to serve as a basis for the diagnosis of acidosis. Acetonuria is exceedingly common with sick children; it is almost regularly present in febrile disease and in any condition in which temporary inanition or starvation occurs. Very seldom is the production of the acetone bodies sufficient to cause a depletion of the alkali reserve. From acetonuria alone the diagnosis of acidosis should not be made, though where the amount in the urine is very large, it should inspire a careful examination for additional evidence of acidosis. Severe and fatal acidosis may occur with no overproduction of the acetone bodies. Their absence from the urine is no evidence that acidosis is not present. Recently Marriott, Hoessler and Howland have called attention to a method of determination of acidosis that occurs with the nephritic state. They state that the acidosis met with in nephritis is unlike that of diabetes; namely, an accumulation of acetone bodies; it is rather due to a failure to regulate the formation of acid substances by the kidneys, a failure to eliminate acid phosphates. Their method looks to the estimation of the inorganic phosphates in the blood. The normal figure expressed in terms of phosphorus varied from one to three and a half mg. to the one hundred c. c. of blood. In nephritic acidosis, they found it increased invariably to many times the normal, as much as twenty-three mg.

The definition proposed by Henderson and quoted by Austin and Jonas for acidosis—is any condition in which the buffer substances of the blood and body fluids are reduced below the normal. Henderson calls the sodium phosphate and sodium carbonate (phosphoric acid and carbonic acid) of the blood and body fluids buffer substances.

Finally, Christian states the most delicate test of renal damage that we possess is the presence of albumin and casts, leucocytes or red blood cells in the urine in varying combination. They are never absent in all of several specimens on different days if there is renal damage—though single examinations may fail to reveal any even in patients with severely damaged kidneys. Their presence does not justify the diagnosis of nephritis unless supported by other data, though their continued absence justifies the conclusion that the kidney is free from nephritis (a diffuse, progressive, degenerative, proliferative lesion of renal parenchyma or interstitial tissue or both).

HYPERTENSION.

Hypertension, as shown by Schneider, may be due to many causes. We are now interested in only one phase of the subject—namely, that type of chronic vascular hypertension which has been called primary vascular hypertension, essential benign hypertension, essential hyperpiesia of Albutt, Gull and Sutton's disease. These cases may show a high blood pressure for many years without definite

urinary findings, and with surprisingly few symptoms. Eventually after many years, these patients do show some capillary fibrosis, with an increase in cardiac failure and increase in renal insufficiency, and at autopsy show extensive thickening of the small arteries and the changes in the kidney look as if they had come as the result of the arterial disturbance. Many other patients with hyperpiesia appear to die with the same combination of signs and symptoms before the peripheral vessels (except the larger ones) show any appreciable change. Gull and Sutton's disease probably represents the advanced or late stages of Christian's primary vascular hypertension.

In a study of one hundred cases of hypertension, Schneider found twenty-six arteriosclerotic, sixteen diffuse nephritic, twenty-five granular kidney, two climacteric, seventeen benign, one surgical kidney, two cystic kidney, four vascular syphilis, three thyrotoxic and four were asphyxial.

Riesman and Hopkins have recently emphasized the cases of hypertension occurring in women between forty and fifty years of age. Some of these women have had many children, some none at all, some showed urinary findings and had symptoms, others had no complaints traceable to the high blood pressure—and got along very well on a regulated diet and rest. Some of these climacteric patients were relieved by the administration of benzyl-benzoate. (Macht), corpus luteum and thyroid. The nitrates and iodides are not beneficial. The blood chemical tests in these cases are normal or nearly normal—the urea N, uric acid, and creatinine are not noticeably increased. At times the hyperpiestic heart becomes decompensated and then some medical treatment is necessarily indicated. It is to be remembered, therefore, that the chronic nephropathies are not to be held accountable for all cases of vascular hypertension—although nearly all cases of persistent high blood pressure eventually do show some renal sclerosis and cardiorenal disturbance.

Clifford Albutt, in 1903, called attention to the fact that the hypertension in a certain proportion of cases was primary and the sclerosis secondary, although the prevailing opinion held at that time was that hypertension was always secondary to arteriosclerosis or nephritis.

Stengel, in 1914, dwelt on the occurrence of cases of arteriocapillary fibrosis (Gull and Sutton's Disease) and noted cases of primary arterial or arteriolar disease with insidious onset. Meara (1), described cases of essential hypertension occurring in ruddy, stocky patients with plethoric habits, and active temperament.

Essential hypertension, or Albutt's hyperpiesia, is essentially chronic in course and ends ultimately in a definite nephritis with sclerosis of the renal vessels, cardiac hypertrophy, and arteriosclerosis, the end result being either cardiac failure, or an arterial accident, cerebral or coronary. These patients rarely die of uremia. Usually they are apparently in robust health, have a florid complexion, are plethoric, and have excellent appetites. These cases usually begin in late middle life. The earliest complaints are increasing dyspnea on exer-

tion and sometimes precordial pain. Meara reports a case of this type in a boy eight and one half years old, in whom the trouble began at the age of five years. After all, these cases may be in the prealbuminuric stage of chronic interstitial nephritis (Mahomed) or the presclerotic stage of arteriosclerosis (Huchard).

OTHER TESTS.

Indigocarmin and methylene blue (from five to fifteen minims) in five per cent. solution when injected into a patient will under normal circumstances color the urine blue in an hour and in twenty-four to twenty-eight hours the dye is completely eliminated. In nephritis the excretion begins later and lasts much longer—several days.

Iodide of potassium, seven and one half grains, when given the excretion of iodine in the urine lasts about twenty-four to thirty-six hours in healthy persons, while in nephritis this may last for four or five days (F. Müller).

Rowntree and Geraghty's phenolsulphonephthalein test has now become the one most commonly used. Phthalein ampoules containing the monosodium salt, in sterile solution (.006 in 1 mil.) can now be obtained, and the Dunning colorimeter is on the market. For the rapid estimation of urea, in the urine and in the blood, urease tablets (twenty-five mgm. may be used). Rapid acidosis testing outfits for estimating the alkali reserve of the blood, the alveolar air carbon dioxide tension, and the hydrogen ion concentration can also be obtained at moderate cost.

The electric conductivity in nephritic urine is often diminished, and the same is true of the blood. The resistance to electric conductivity of a fluid depends upon the amount of electrolytes—i. e., dissociated ions of inorganic salts contained therein. Increased concentration of the salts adds to the electric conductivity.

The freezing point and boiling point of a solution are dependent upon the number of molecules present in it. The fewer the solid constituents the kidney excretes, the less will the freezing point of the urine be below the freezing point of distilled water. Under normal conditions this lowering is about 1° to 2.3° C. below 0°. If it is less than 1° C., an insufficiency of the kidneys is probable.

The freezing point of blood normally is about 0.56° C. below that of water. In disease of the kidneys it sinks lower. In uremia it is as low as 0.70°—75° C.

BLOOD PRESSURE.

In estimating the blood pressure in my cases I always use the auscultatory method of Korotkow. This is the simplest, most satisfactory and accurate method. In cases where the heart is irregular in force and rhythm it becomes impossible to make accurate observations of systolic and diastolic pressure. In such cases Warfield advises taking the average reading between the point where the strongest beat is heard and the point where practically all beats are heard as the systolic pressure. The diastolic pressure is best taken at the point where no sound is heard except the occasional sound produced by an excessively strong beat. The first

audible sound occurs at systolic pressure; the diastolic pressure should be read at the sudden transition of the third clear tone to the dull fourth tone and just before the disappearance of all sound.

Diastolic pressure is important as it measures the peripheral resistance; the pulse pressure measures the actual head of propulsive force in the arteries at the base of the heart. Normally, the pulse pressure is forty to forty-five mm. of mercury. The cause of hypertension is not exactly known. Macht and Voegtlin have isolated a crystalline substance from human blood which they regard as a lipoid and related to cholesterin. This substance was recovered from the cortex of the adrenal gland. There may be something in the circulation, therefore, that produces constriction of the vessels. Speaking of hypertension in women Riesman says it may be set down as a general rule that hypertension in women under thirty-five years of age is practically always nephritic, it gives a bad prognosis, much worse than any other form of hypertension.

UREMIA.

There are two forms of uremia. Chloridemia, eclampsia of Volhard, is due to arterial hypertension, and edemas caused by retention of water salines—i. e., mechanical in origin. This is a pseudouremia. Azotemia, or true uremia, is due to some excess accumulation of toxic substances. These poisons are largely nervous poisons. Uremia holds the same relation to nephritis as coma to diabetes. The real cause of uremia is not known.

Traube believed uremic symptoms were dependent upon an acutely developing edema of the brain and consequent cerebral anemia. Frerichs assumed that through fermentation, the urea in the blood of nephritics was converted into carbonate of ammonia. Some experiments seem to point to potassium salts as the poisonous agents. Some workers laid the blame for the condition on extractive matters, as creatinin. Bouchard, Acoli and others thought that the urotoxins (alkaloid substances), nephrolysin, nephrotoxins, caused the kidney cells to break down and act as poison (product of disintegration of the tissues) Brown-Séguard. Some traced the uremia to a disturbance in renal internal secretion.

Noncoagulable nitrogen, the nitrogen remaining in the blood after the complete precipitation of albumin, may play a part. Hughes and Carter conclude that the poison is of an albuminous nature. Rose Bradford showed an extraordinary increase in the production of urea of the nitrogenous bodies like creatinin and creatin, and that it profoundly influenced the metabolism of muscle tissue.

Fleischer found urea in the saliva and sputum of a uremic patient. Schottin first described a coating (lustrous scaly) of urea on the skin and the sides of the nose in uremia. Urea does not cause uremia. Widal thinks it does. Ammonia nitrogen does not cause uremia. Martin Fischer states that an acid intoxication of the brain caused edema of the brain cells and uremic symptoms resulted.

There is an accumulation of rest nitrogen (non-coagulable nitrogen) in the blood, in uremia with convulsions, but it has not been proved to be the

cause of uremia. Foster thinks he has discovered the causal toxic crystalline substance in uremia. Indicanemia is not the cause. Foster describes several types of uremia: 1. Retention type of uremia, due to obstruction of ureters (complete occlusion) or if a surgeon by mistake removes an only kidney, or if both kidneys do not functionate, death occurs in stupor and without convulsions. 2. Cerebral edema type occurs in acute parenchymatous and glomerular nephritis. Symptoms of cerebral compression due to edema of the brain, and death occurs without convulsions. 3. Toxic or epileptiform or classical or convulsive type, occurs with local and general twitchings and convulsions. It is in this type that Foster thought he discovered the causal poison of uremia.

SYMPTOMS OF UREMIA.

The pulse is often very slow, forty to fifty, before the appearance of severe symptoms. There is a disturbance of the cerebral visual centres, particularly of the occipital cortex, resulting in amaurosis. Delirium and maniacal or melancholic states occasionally follow uremic coma. Uremic vomiting is often persistent, it may be central in origin, but it is also due to gastric irritation from eliminated urea.

Uremic diarrhea is provoked by the carbonate of ammonia arising from the urea in the intestines. The disturbances in uremia are almost exclusively cerebral and in the main located in the cortex of the brain. They are probably due to a direct injury of the nervous elements, possibly also to spasm of the blood vessels.

The most characteristic symptom of severe uremia is the uremic convulsion. Headache, precordial distress, vomiting, peculiar restlessness, itching of the skin, are important symptoms in milder forms of uremia. Uremic amaurosis usually remains after recovery from the convulsions and usually develops quite rapidly. A lustrous scaly coating of urea may be observed on the sides of the nose in these uremic cases.

Fischer says the "consequences of kidney disease are not consequences but are the same thing as the kidney disease manifested in the different organs of the body and all due to the same poison which originally produced the kidney change." He attributes the headache, stupor, coma, and convulsions of uremia to an edema of the brain, the changes in sight to an edema of the optic nerve or retina, the vomiting to an edema of medulla and the general edema to a swelling of the body tissues generally, all induced through the same poison circulating through the body and responsible for the edema of the kidney (nephritis). He believes water is the only true diuretic.

Nervous symptoms.—Uremic hemiplegia is characteristically transient, changes may occur in a few hours. These cases must be differentiated from cerebral hemorrhage and thrombosis. Aphasia which is renal in origin clears up commonly, with an improvement of the condition. It must be remembered, however, that a uremic patient may also have a cerebral hemorrhage.

(To be continued.)

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL

tation through the mail as second class matter.

NEW YORK, SATURDAY, AUGUST 21, 1920.

PHYSICIAN AUTHORS—DR. DAVID
RAMSAY.

It is said that Napoleon during his exhaustive military campaigns was able to thrive on five hours' sleep a night, and sometimes less, and deemed more than that amount of slumber unnecessary. There have been those who required even less sleep, and one of these was that indefatigable patriot of the Revolutionary period, Dr. David Ramsay. It is related that Dr. Ramsay would sleep only four hours a night, arising before daylight and devoting his entire time to hard, systematic work. It is not surprising that with all this intensive industry Dr. Ramsay was able to take care of a large medical practice and at the same time dash off something like thirty volumes of history and miscellaneous writings, in addition to taking an active part in all public and philanthropic enterprises in his home city, Charleston, South Carolina.

Dr. Ramsay's numerous volumes of Revolutionary history are not only excellent narratives in themselves, but they have also been veritable storehouses of information from which succeeding historians have been able to gather a vast amount of material. He was peculiarly fitted to give to America its first written accounts of the War of Independence, for he was not only an exceptional man, but also one who enjoyed exceptional advantages. As a member of the Continental Congress he had access to all official documents, and he tells us in his preface that he went carefully

through these, gathering notes and data. Similarly, he made a careful perusal of all Washington's letters and those of the other general officers and members of Congress. Throughout the Revolution, despite his numerous patriotic activities, he busily gathered material for the volumes of history which he wrote after freedom had been attained. As a further help in the compilation of his histories, Dr. Ramsay was blessed with a retentive memory and a fine sense of discrimination, and he was a keen observer of men and events. As a writer he was lucid, direct and forceful, and his descriptions of battles and characterizations of men were clear cut, vivid and exact.

In a way, Dr. Ramsay had been a sort of child prodigy. Born on a farm in Lancaster County, Pennsylvania, on April 2, 1749, of Irish parents, he displayed rare talents at an early age, and was uncommonly proficient in his studies at school. When he was twelve years old he became a tutor in an academy at Carlisle, Pa., and after a year in that occupation he entered the College of New Jersey, now Princeton University, from which he was graduated in the class of 1765. He then began teaching school in Maryland, and it was not until after several years of this that he decided to become a physician. He was graduated from the University of Michigan as an M. D. in 1773, and settled in Charleston, where he rapidly built up a large practice.

Although Dr. Ramsay had been an ardent patriot in his younger years, it was in Charleston that he gained prominence throughout the colonies by reason of his unflinching advocacy of the colonies' rights. The part he played in the Revolution was a large one—as member of the South Carolina Senate, as member of the Continental Congress, as field and hospital surgeon, and in various other capacities. When the British captured Charleston in May, 1780, Lord Cornwallis ordered that Dr. Ramsay be put in prison at St. Augustine, Fla., to curb his anti-British activities. As a public speaker and member of the Council of Safety at Charleston, Dr. Ramsay had long been a thorn in the side of the British. He was detained at St. Augustine eleven months. Two years later he was elected to the Continental Congress and reelected in 1785. During his second term he served for one year as president *pro tempore* during the illness of the famous John Hancock.

The History of the Revolution in South Carolina was Dr. Ramsay's first published work, issued in

two volumes in 1785, followed four years later by his *History of the American Revolution*. Dr. Ramsay wrote the first *Life of Washington* (published in 1807), with whom he was personally acquainted, and the biography stands today as one of the best and most authentic of the numerous biographies of the Father of His Country.

The most pretentious of Dr. Ramsay's works was his *Universal History Americanized*, in twelve volumes, which included three volumes of his *History of the United States from the First Settlement in 1607 to 1808*.

Dr. Ramsay's writings included three works of more or less direct interest to the medical profession—one entitled *The Means of Preserving Health in Charleston and Vicinity*, published in 1790; a *Review of the Improvements, Progress and State of Medicine in the Eighteenth Century*, published in 1802, and a *Eulogium of Dr. Benjamin Rush*, published in 1813.

Despite his literary activities, Dr. Ramsay continued his professional practice in Charleston from 1786 until his death in 1815. His influence seems to have been great in every department of life. He was always in demand to address public gatherings, and is reputed to have been a forceful speaker. He was twice married, his first wife being Frances, the daughter of the Rev. John Witherspoon, president of Princeton University, and the second wife Martha, daughter of Henry Laurens, of Charleston, a woman of rare accomplishments, as extracts from her diary, included in Dr. Ramsay's *Memoirs of Mrs. Martha Laurens Ramsay*, show.

Dr. Ramsay, notwithstanding a tremendous expenditure of energy throughout his life, was said to be in vigorous health when he was shot by a lunatic against whom he had testified as an alienist. He died as a result of his wounds on May 8, 1815, at the age of sixty-six.

THE TRUE BASIS FOR PENAL REGULATION.

Genuine self interest can never stand in antagonism to the best and most workable altruism. It is rather the basis of the latter. Honest and thorough investigation of an individual self or of society would not fail to recognize this. But the individual self has lazily and timidly stopped short of such investigation, and so has collective social understanding. Stopping less than half way, both have failed to penetrate to real motives or to the basis out of which all motives primarily arise. Here their sincerity must be put to the test, and their genuine self interest find not only its natural justifi-

fication, but its origin as a spring for all service rendering behavior. In the sphere of penal regulations and activities we are slowly realizing how seriously the race has allowed certain partial conceptions to obstruct the more honest penetration which involves time and trouble, a good deal of both. Such partial conceptions dominate the thought and the method of civilized society.

Enrico Ferri, writing of The Reform of Penal Justice in Italy (*Archivio di Antropologia criminale, Psichitria e Medicina legale*, Vol. XL, No. 1, 1920), says that two principles have formed the basis of the administration of justice. Neither of these has truly served the principles of self interest, for they have been only blindly applied to this end. The two principles which are in play, the writer says, are that of defense of the state against the individuals who threaten it and that of penalty measured only according to the gravity of the offense. Society in its attitude toward penal questions has forgotten or completely lost sight of its own best defense, its own best interest, as contained in an understanding of the real nature of the criminal and of the crime from his point of view. The time and trouble involved in this are more than society is in the habit of spending upon any of its questions or upon any one of its individuals, except in the negative way of patching up damages done, repairing the ravages due to a crime, and putting into action the extensive machinery of apprehension and punishment of the offender. The trouble of investigation that would lead to preventive action in the case of the individual delinquent and to a thorough apportionment of the treatment of each delinquency in order to get the best positive returns in the long run for society itself has not seemed worth while. This study from Italy reminds us again that such unreasonableness and lack of real self interest on the part of society are coming to be recognized as the starting point for some more effective manner of viewing the question.

The writer refers to Christ's injunction that one man shall not judge another. The logic of this command lies in the fact that one man cannot judge another. He has not possession of the elements on which such judgment could be based. It is necessary to know the internal world which belongs to the offender really to pass sentence that should fit the crime. This includes a knowledge of the individual's heredity, of the environment, intrauterine and extrauterine, by which his early life was surrounded, and of all his later family and social surroundings. Could this all be known, the question for social regulation would not yet be one of

punishment. Who is even society, one might ask, to mete out measure for measure, the payment for a social crime? The crime itself and its injury to society are not something which can be put in the balance and compensated for. The practical duty, one which serves the interests of every one, and by this alone protects society, is to determine how best to redirect these tendencies, these psychological determinants, which, in addition to environmental pressure, have resulted in criminal acts. Enacted laws against crime can, as the writer states, only partially eliminate the effects of crime. They do nothing toward its causes, and therefore do not defend against repetition.

Alteration of causes can be attained only by the larger psychological knowledge; by providing better social conditions, and aiding the individual in his adaptation to these. There can also be more direct and efficient prevention through police agencies and special educational provision for those who are deficient in adaptive power, because of deficient intellect or otherwise. There should also be personal attention directed toward the condemned from the time of their apprehension to that of the carrying out of their sentence and at their return to society. Agricultural and other colonies are suggested as wise provision for those under punishment. A strong plea is made for special educational training for the officials who have the penal work in hand. Psychology, medicine, anthropology, and criminology should be in their course of study.

TABES AND FACIAL PARALYSIS.

When facial paralysis occurs during tabes a certain number of questions are to be considered if a correct diagnosis and prognosis are to be made. The first question, is there really facial paralysis, simple as it appears may necessitate a long and minute examination, and for making a conclusion the state of contracture of the face, the exaggeration of the asymmetry on the slightest movement, the deviation of the tongue, and spasmodic twitching of the eyes and lips must be looked into. In some cases the asymmetry that one is prone to attach to the paralysis may be the effect of ataxia of the face. The patient may also limit the movements on the side of the face, either because of the violent pain occurring with each motion or because of a true paresis indirectly related to the involved sensitive portion of the trigeminus. Finally, tabetic hemiplegias exist, but their description is too well known to require comment.

If facial paralysis really exists, the second question is whether the paralysis is really tabetic. In

some cases paralytic associations may distort the face so that a pseudobulbar paralysis may be considered, in which case the reflexes are not abolished. A glossolabiolaryngeal paralysis might also be diagnosed, but here there are no ocular manifestations or sensitive or sensory phenomena. But confusion generally is not possible and the real point to settle is whether the facial paralysis is tabetic or is a facial paralysis occurring in an ataxic subject. A tabetic is both a nervous and syphilitic subject and each of these conditions is susceptible to facial paralysis.

As a nervous subject he may be hysterical and a true hysterical paralysis may develop, although this is rare. A careful study will always detect some peculiarity, such as irregular distribution occasionally supplanted by true spasmodic paroxysms almost constantly accompanied by sensory manifestations. On the other hand, hysterical facial paralysis is a manifestation of a hysterical syndrome, always serious and frequently giving rise at the same time with the facial hemiplegia to a total hemiplegia or a hemianesthesia. In the ataxic there may develop a facial paralysis *a frigore* from the most trivial causes. It is usually easy to recognize a nuclear paralysis and to differentiate it from a purely neuritic paralysis; the distribution is not the same, the evolution is in every way different; the extent and the intensity, especially at the onset, may be infinitely more marked in a *frigore* type. On the contrary, it is a delicate matter to differentiate a pretoxic paralysis from facial paralysis. The benign characters and the rapidity of evolution are not the appanage of tabetic paralysis only; they are merely presumptive characters. But always when a tabes is distinctly evident as well as the symptoms of the onset—fulgurating pains, the Argyll Robertson, Westphall, and so on and above all if the tabes appears to claim this somewhat special character that Brissaud has described under the name of paralytic tabes—the physician will be authorized to relate every instance of nonsymptomatic facial paralysis to the tabes in evolution.

The tabetic being a syphilitic, there are several good reasons for a facial paralysis developing during the secondary phase of syphilis, as tabes is always a late manifestation, but during the tertiary phase syphilis has multiple means of producing functional impotency of the facial nerve. First, there is the basal meningitis which involves the third and fourth cranial pairs. The auditory nerve frequently gives rise to hemianosmia with preservation of tactile sensibility of the nasal mucosa on the same side; it also provokes an extremely marked leucocytosis as revealed by examination of the cere-

brospinal fluid. Luetic meningeal gummata may be seated at the point of exit of the facial nerve, more rarely over the convexity of the brain; occasionally even a large surface of the meninges is involved by the gummatus or sclerogummatous process. Much more rarely the nerve itself appears to be directly involved, but gummatus neuritis is so exceptional that from the viewpoint of diagnosis it need scarcely be taken into consideration. Great consideration should be given to bone lesions—exostoses, gummatus periostides—compressing the seventh pair in its course along the Fallopian aqueduct. Such cases are easy to eliminate because tabetic facial paralysis is exceptionally isolated. However, the fact that the patient has tabes will be greatly in favor of a diagnosis of facial hemiplegia and above all the test by treatment—positive in syphilitic lesions, negative in tabes—will be conclusive.

As to the third question, namely the nature and origin of the paralysis, there will be no difficulty in typical cases. The rapidity of evolution, the general involvement of the face, the appearance of the paralysis at the onset of the tabetic symptoms, the suddenness of appearance and disappearance, and their benign course are all characters—although relative—which assign them to a neuritic origin. Their incurability, progress, the exclusive involvement of the lower territory of the face, the association especially with other paralyzes of nuclear origin, are elements of almost certain nuclear origin.

News Items.

Tri-State Medical Meeting.—The Tri-State District Medical Society of Iowa, Illinois and Wisconsin will be held October 4th to 7th at Waterloo, Iowa.

Minnesota Medical Meeting.—The annual meeting of the Minnesota State Medical Association will be held September 29th to October 1st in St. Paul.

Southwest Medical Meeting.—The Medical Association of the Southwest will hold its fifteenth annual session September 27th to 29th at Wichita, Kan., under the presidency of Dr. E. F. Day, of Arkansas City, Kan.

Dysentery in Poland.—Dispatches from abroad state that dysentery is epidemic in the Polish army. At one Red Cross station where about 4,000 men are received daily, four fifths of the arrivals are said to be suffering from dysentery.

Fiske Fund Prize Awarded.—The Fiske Fund Prize of the Rhode Island Medical Society has been awarded to Dr. Allen G. Rice, of Springfield, Mass., for his dissertation on Surgical Lessons of the Great War.

Death of Professor Guyon.—Word has come from Paris of the death of Professor Feliz Guyon, senior surgeon of the Hôpital Necker, and a former president of the Academy of Sciences and the Academy of Medicine, Paris.

Child Hygiene Conference.—The American Child Hygiene Association will hold its annual meeting October 11th to 13th in St. Louis. The Central States Pediatric Society, which also meets in St. Louis October 13th and 14th, will hold a joint session with the first mentioned association.

Death of Professor Politzer.—Professor Abame Politzer, the noted otologist of the University of Vienna, died on Thursday, August 12th, in his eighty-fifth year. Dr. Politzer was the teacher of many American postgraduate students in Vienna.

Archives of Surgery.—The first number of the *Archives of Surgery* has recently been issued by the American Medical Association. It will contain papers which have been read before the surgical section of the Association and also original articles pertaining to research and investigation in the field of surgery.

Award of Cameron Prize.—The Cameron prize of the University of Edinburgh has been awarded to Sir Robert Jones in recognition of the highly important advances he has made in orthopedics and his many valuable contributions to the literature of the subject during the past five years. The prize has not been awarded since 1915, when it was given to the late Sir Lauder Brunton.

French Asylum Transformed.—The National Asylum at Charenton, France, is to be gradually transformed to a giant maternity home and crèche. At present 500 mental patients occupy the asylum, which has accommodation for 1,500. These 500 will remain in one wing of the vast building, and as they die out—the mortality rate is high—their places will not be filled. From now on 1,000 beds will be reserved for the Institute of Puericulture, providing accommodation for about that number of recently confined women, who will stay there with their infants for an average of two months. The number of these occupants will gradually increase in proportion as the others disappear.

Personal.—Dr. John M. Finney, of Baltimore, has recently returned from Europe, where he attended the Interallied Surgical Congress at Paris.

Dr. V. J. Harding, associate professor of biological and physiological chemistry at McGill University, has been appointed professor of pathological chemistry in the University of Toronto.

Dr. W. Thurber Fales, of Malden, Mass., has been appointed instructor of biology and public health in the medical school of the Johns Hopkins University.

Dr. S. Burt Wolbach, professor of pathology and bacteriology at Harvard Medical School, has returned from Poland, where he spent six months studying typhus.

Dr. Sebastian Recasens, of Spain, is on a visit to this country for the purpose of studying radium treatment of malignant diseases.

Book Reviews

MARK TWAIN ANALYZED.

The Ordeal of Mark Twain. By VAN WYCK BROOKS, Author of *Letters and Leadership*, etc. New York: E. P. Dutton & Co. Pp. vii-267.

Two questions force themselves upon the reader of this book. How many countrymen of Mark Twain would subscribe to Brooks's conviction of the beloved writer's failure and recognize in him a pessimistic sense of defeat struggling with his naturally cheerful nature? This presses the second question: Who among us would be roused to conscientious self-examination to see if he too had fallen under the spell of public opinion to the detriment of creative ability? No thoughtful person can deny the realization of a manysidedness in the attitude of Mark Twain, the acknowledged humorist of the American people, which discloses traits that are not those of the satisfied man. When his life and work are closely studied it is discovered that his uncertainty of attitude is apparent not only in the latter years of life that suffered many external losses, not alone at times of financial collapse. It has been present in the man all through his personal career. It has made of the external griefs, of the losses and successes only episodes which represent the attitude with which the man took up his life and work. They are the results in large part at least of his confused position in regard to himself and the world about him.

There is something that puzzles the admirer of Mark Twain; something that detracts from the power that should be found in his work. One who had such ability to win the attention of a people, to hold and extend it into wider circles should have left many a stimulating message. There were times when Mark Twain stirred his readers to such expectation, there were writings which suggested that the contented would have to don their armor of protective convention. Those restless for advance almost found a leader in him but the promises were little fulfilled. Instead of this evidences of a hindering of his vast powers are found in his writings in his populace winning speeches in his business ventures in his successes as well as his conspicuous failures. His works reveal themselves for the most part as only a vast flood of effort to please to satisfy an uncritical public. The public to which he catered cared more for its fixed conventions under which it obtained its material success and maintained its established literary complacencies than to be roused to new development.

Brooks shows that this is largely the result of the period to which Mark Twain belonged, the era of a tremendous effort and a too engulfing type of success. Material standards were those of the nation and individuals bent themselves toward them. Mark Twain and his associates almost forgot the urgency of the creative instinct. They overlooked the fact that it represents the more urgent need of the individual as well as his chief avenue of service to society. But no; Mark Twain himself did not entirely forget. Again and again he gives evidence of this. In the reports of his

biographers as well as through the often uttered thought in his own writings, in his letters, wherever Mark Twain spoke, this man of such apparent success revealed the suffering of an impaired spirit. His testimony was constantly that of a house divided against itself, the house of his inner soul. "You observe that under a cheerful exterior I have got a spirit that is angry with me and gives me freely its contempt." This he writes to his mother. It is to her that Brooks points his readers to witness the heavy hand of pressure laid by this impressive woman upon the child soul. Brooks touches slightly upon the elements of libido fixation which led the boy to accept such a strong limitation by another person. He tells us of the mother's capacity for loving which her husband failed to satisfy. He mentions the sensitive boyhood oppressed by the boy knew not what sense of naughtiness and guilt. At any rate these things rendered him so impressionable, so heartbrokenly sensitive at his father's coffin that he permitted the signing of himself away to his mother's wishes. He subscribed to the fixed conventionality which she represented and stifled the freedom to create and to express according to the sincere dictates of his own nature. His later life throughout his varied career was a successive repetition of such acknowledgment of the force of convention. He submitted to the authority of money or of accepted literary taste. He was a life long victim of all sorts of worshipped standards. These failed to encourage, they actually forbade the launching of new thoughts. A soul inwardly aware of its own power could not permit itself the free expression of its convictions and send them forth as regenerating ideas.

Such are the secrets of Mark Twain's unrest with himself and of his failure in vigorous messages. His artist's spirit had been turned aside from its service to his own age and the future. He himself valued most that time in his life when in the position of river pilot on the Mississippi he stood above public opinion and was able for once to be himself. Here and there in his later life he tried to attain again this freer exercise of himself but it was with only partial success. He revealed a pathetically undue exaggeration of the furor that such possible free expression would produce about the heads of his descendants. Great he was, but his genius never dared find and exercise itself. Hence its flooding in many directions where it stood at a high water mark but never flowed on to wear new channels. He dared not upheave the calm exterior of society. Thus he could do little to ease the pain of a hindered life. He dared not attack the system of things and so he remained, Brooks says, "the playboy to the end, divided between rage and pity, cheerful in his self-contempt, an illusionist in the midst of his disillusion." In this he is the typical American unappreciative of the self-responsible soul of the artist. Thus Brooks arraigns America itself in this presentation of Mark Twain. The latter was partially just disturbingly

aware of his creative spirit. Too many of his fellow citizens are unaware of power and responsibility and to too great an extent this is true of American society in general. This well written study therefore of this national literary hero is a wholesome stimulus to sober selfconsideration and national testing, as regards the freedom of the creative spirit from without and from within.

ORAL SURGERY.

Oral Surgery. A Treatise on the Diseases, Injuries, and Malformations of the Mouth and Associated Parts. By TRUMAN W. BROPHY, M.D., D.D.S., LL.D., Sc.D., F.A.C.S., President, and Professor of Oral Surgery, Chicago College of Dental Surgery; Oral Surgeon to St. Joseph's, Michael Reese, and Other Chicago Hospitals; Consulting Oral Surgeon to the Presbyterian Hospital. With Special Chapters by MATTHEW H. CRYER, M.D.; G. HUDSON MAKUEN, M.D.; WILLIAM J. YOUNGER, M.D.; F. W. BELKNAP, M.D.; CALVIN S. CASE, M.D., D.D.S. With Nine Hundred and Nine Illustrations, Including Thirty-nine Plates in Colors. Philadelphia: P. Blakiston's Son & Co., 1918. Pp. xvi-1090.

The history of oral surgery as a specialized branch of medicine and as the first specialty of dentistry is comparatively short and dates back to the influence of James Edmund Garretson, who at the height of his career about seventy years ago commanded the attention of the world with his very important work in surgery of the mouth. Although the care in avoiding mutilation of the external features while performing intraoral operations emanates from Garretson there is today a great deal of mutilation produced by members of the medical profession, who find it a much simpler technic to lift away the cheek for the removal of the superior maxilla than to work through the natural opening.

Truman W. Brophy received his early training from Dr. Garretson, whose influence is immediately shown in the preface of his book when he says that the important principle to be observed is to operate so that the parts will be left in as nearly a normal anatomical condition as possible. That of course is an underlying principle of general surgery, but in no branch of the work is the execution of this principle as vital as in surgery of the mouth and the surrounding parts.

Most important in the crowded material of over 900 pages is the original contribution of Brophy's on the cleft palate. There are few more ugly conditions than the congenital condition of the harelip and cleft palate, regarding which there has been so little understanding. To definitely establish the truth about the cleft, which had long been regarded as a condition of atrophy, was the first move. "A cleft palate," says Dr. Brophy, "is a fissure, a separation of well developed parts, not the result of arrested development nor failure of the normal quantity of tissue to enter into its structure." Upon the recognition of that fact, Dr. Brophy attempted to bring the parts of the superior maxilla together under pressure. The complete success of the operation depends entirely upon the age of the patient at the time of operation, the first three months of life being the most favorable period. The operation today is generally used. It was for a long time

contended that speech, the mechanism of which is largely dependant upon the palate, would not be rectified, and that an obturator would have to be employed but time and the results of the operation have since disproved the belief of the skeptics. The technic of the operation with its many variations is carefully outlined and aided by the many photographic representations.

Much more can be said about the remaining material, the first part of which concerns itself with a consideration of the general conditions of surgery and the second half with those of the buccal cavity and the surrounding parts—material that Dr. Brophy began to collect in 1886 and which he did not publish until 1915, replete with data and photographic and diagrammatic representations to help the student and the practitioner to a better understanding of the subject. Since 1915 six editions of the book have been published; the seventh is now being issued.

MODERN ADVENTURE.

Hills of Han. By SAMUEL MERWIN. Illustrated. Indianapolis: The Bobbs-Merrill Company. Pp. i-365.

Mr. Merwin has done a thing which we have always maintained there was no reason for not doing—he has compounded a thrilling adventure story out of persons and situations which do not strain anyone's credulity. He has done even more, for there is some shrewd psychology in the depiction of his characters. It is, however, not a book which the missionaries will care to read, for one of its chief figures is a missionary, and one of its author's preoccupations is with showing how the rigor of a missionary compound denies fundamental human needs—joy, spontaneity, colorful expression.

This book is interesting as showing what can be done by a writer who does not actually shut his eyes and ears to what is going on in the world. As a tale of adventure *Hills of Han* is full of exciting incidents, mostly violent—the revolt of the Chinese against foreign capital, leading to attacks on all foreigners; the heroics of the rebel student Li Hsien; the creeping by night through mysterious dangers; the fighting about Ping Yang; the background of political intrigue, and the teeming life of the Orient. In addition, however, Mr. Merwin has given us several characters who denote struggle. There is Griggsby Doane who, after years of military faith as a missionary, finds that at forty-five he is full of energy and in the wrong work, and whose bitter struggle against doubt ends in his deciding to begin over again in a primitive, satisfying existence as a common workman. On the other hand there is Jonathan Brachey, the journalist who, embittered by an unhappy marriage, tries to solace himself with solitude and Nietzschean self sufficiency. He, too, finds after he has met Betty Doane, Griggsby's daughter, that he has to start afresh. There is Betty herself, an affectionate, impulsive, artistic temperament, among people who associate joy with vice. The psychological—and in one place physical—struggle between Doane and Brachey is quite as exciting as the shooting up of the missionaries.

One thing more Mr. Merwin has done. He has caught something of the ancient wisdom and the new turbulence of China; there is a rumbling pro-

phesy of the student revolt to come, of the beginnings in China of the class warfare that today is encircling the globe. A very modern adventurer, Mr. Merwin. He seems to have read Freud, and he probably has read something about the class struggle. So many writers of thrilling fiction refuse to know anything about either.

MYSTERY.

The Paradise Mystery. By J. S. FLETCHER. New York: Alfred A. Knopf, 1920. Pp. ix-306.

In these days, when a doctor can be condemned for culpable negligence or exonerated by a learned jury numbering the butcher, baker and artisan, it is refreshing to read of one accused of murdering a man, poisoning another and betraying a friend, calmly going on with his work with the hot breath of slander full on him, and his former associate unkindly running all over the country to prove him guilty. Certainly the poisoned man died of hydrocyanic acid poisoning; certainly the hero—Dr. Ransford—had given him some digestive pills, but he had died immediately, whereas a fellow practitioner explains that, as the pills were sugar coated, they could not take effect instantly. (Science usually appears as the guardian angel in mystery stories.) In the end an aged citizen who is highly esteemed is proved the murderer, but he is so angry with the treacherous associate, thinking he has betrayed him to the police that he shoots him dead and poisons himself—no sugar coating this time—leaving nothing for the police to do but rush away for Dr. Ransford to come and say the men are dead. Not a difficult task, nor was that of reinstating himself in the neighborhood's esteem any harder. The story is well told, because the mystery is kept up right to the end.

THE ORIENT.

Civilization. Tales of the Orient. By ELLEN N. LA MOTTE. New York: George H. Doran Company, 1919. Pp. 231.

Tuberculosis is an insidious, often an unrecognized disease, and many years of Miss La Motte's life were spent in directing national efforts to fight it, and the habit of thoughtful consideration of an evil cannot be suddenly broken nor small indications—negligible to the laity—be ignored. So it came about that when working in the French War hospitals, when traveling in Japan she saw, underneath the pomp and glory of war, underneath the picturesqueness of the East, much that was remediable especially in military camps and the evils of the opium trade, therefore much to be not only deplored, but exposed to the sterilizing light of publicity.

In the book giving tales of the Orient she is, in reality, attacking a morbid condition, which with grim sarcasm, she calls civilization. The stories she tells are good, not a few bare facts with scenery spread over to hold them together. *Canterbury Chimes* and *Homesick* are especially good, but the undertone in all asks What has civilization done to place the peoples of the Orient on a higher level and induce that sympathy and understanding too long withheld by the Western world?

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE LIFE OF ROBERT OWEN. By HIMSELF. With an Introduction by M. BEER, Author of *A History of British Socialism*. New York: Alfred A. Knopf, 1920. Pp. xiii-352.

GOTTFRIED KELLER. Psychoanalyse des Dichters Seiner Gestalten und Motive. Von Dr. EDUARD HITSCHMANN. Wien: Internationaler Psychoanalytischer Verlag, G. M. B. H., 1919. Pp. vii-125.

YOUTH AND EGOTATRY. By PIO BAROJA. Translated from the Spanish by JACOB S. FASSETT, JR., and FRANCES L. PHILLIPS. Edited, with Introduction, by H. L. MENCKEN. New York: Alfred A. Knopf, 1920. Pp. v-265.

COLUMBIA UNIVERSITY BULLETIN OF INFORMATION. Annual Report of the President and Treasurer to the Trustees with Accompanying Documents for the Year Ending, June 30, 1919. Illustrated. New York, 1920. Pp. v-499.

ELECTRIC IONIZATION. A Practical Introduction to Its Use in Medicine and Surgery. By A. R. FRIEL, M.A., M.D. (Dub.), F. R. C. S. I., Aural Specialist, Ministry of Pensions, London District, etc. Illustrated. New York: William Wood & Co., 1920. Pp. ix-78.

THE NEW PHYSIOLOGY IN SURGICAL AND GENERAL PRACTICE. By A. RENDLE SHORT, M.D., B.S., B.Sc. (Lond.), F. R. C. S. (Eng.); Examiner in Physiology for the F. R. C. S., etc. Fourth Edition, Revised and Enlarged. Illustrated. New York: William Wood & Co., 1920. Pp. xi-291.

DIAGNOSTISCHER LEITFADEN FÜR SEKRET-UND BLUTUNTERSUCHUNGEN. (Theoretisches und Praktisches.) Von Dr. C. S. ENGEL, Sanitätsrat, Arzt und Laboratoriumsleiter in Berlin. Mit 144 Abbildungen und 1 farbigen Tafel. Zweite, völlig umgearbeitete Auflage. Leipzig: Verlag von George Thieme, 1920. Pp. xv-303.

THE DUODENAL TUBE AND ITS POSSIBILITIES. By MAX EINHORN, M. D.; Professor of Medicine at the New York Postgraduate Medical School; Visiting Physician to the Lenox Hill Hospital, New York. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920. Pp. xiii-122.

HEART TROUBLES: THEIR PREVENTION AND RELIEF. By LOUIS FAUGÈRES BISHOP, M.A., M.D., Sc.D., F.A.C.P., Professor of the Heart and Circulatory Diseases, Fordham University School of Medicine, New York; President of the Good Samaritan Dispensary; Physician to the Lincoln Hospital, etc. Illustrated. New York and London: Funk & Wagnalls Company, 1920. Pp. xvi-422.

AN INDEX OF SYMPTOMS. With Diagnostic Methods. By RALPH WINNINGTON LEFTWICH, M.C., Late Assistant Physician to the East London Children's Hospital; Author of *Tabular Diagnosis*, etc. Seventh Edition, Revised by H. N. WARNER COLLINS, B.Sc., M.R.C.S., L.R.C.P., Radiographer to the Putney and Chiswick Hospitals; Deputy Radiographer to the Evelina Hospital. New York: William Wood & Co., 1920. Pp. xii-595.

LEHRBUCH DER VOLKSERNÄHRUNG NACH DEM PIRQUET'SCHEN SYSTEM. BEARBEITET VON J. HEUSSLER, E. MAYERHOFER, FRAU R. MIARI, E. NOBEL, ER. OBERLEITNER, CL. PIRQUET, R. SCHNEEWEIS, R. WAGNER. Herausgegeben von Priv. Doz. Dr. E. Mayerhofer, Assistent der Universitäts-Kinderklinik; und Prof. Dr. C. Pirquet, Vorstand der Universitäts-Kinderklinik in Wien. Mit 32 Abbildungen im Texte. Wien und Berlin: Urban & Schwarzenberg, 1920. Pp. vi-299.

DEMENTIA PRAECOX AND PARAPHRENIA. By Professor EMIL KRAEPELIN, of Munich. Translated by R. MARY BARCLAY, M.A., M.B., from the Eighth German Edition of the *Textbook of Psychiatry*, vol. iii, Part II., section on the Endogenous Dementias. Edited by GEORGE M. ROBERTSON, M.D., F.R.C.P. (Edin.), Lecturer on Mental Diseases in the University of Edinburgh and Physician to the Royal Asylum, Morningside. Illustrated. Edinburgh: E. & S. Livingstone, 1919. Pp. x-331.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

THE TREATMENT OF SURGICAL SHOCK.

By JOSEPH W. WALSH, M. S., M. D.,
Brooklyn, N. Y.

The condition of shock was known to the ancients, but the term shock was introduced in 1795 by James Latta to designate the condition following severe injury. Shock is really a general depression of the vital powers, the result of an injury or profound emotion. It may be slight or transient or severe and prolonged. It is usually sudden in onset, but may come on gradually, and possibly may produce almost instant death. There are many theories as to the cause and nature of shock, none of which is entirely satisfactory. I shall, however, discuss only its treatment.

There are various forms of shock and some cases call for special methods of treatment. We have apathetic shock, also delayed shock which comes on several hours after an injury or a violent emotional disturbance. This latter form is often seen in people who have passed through a railroad accident. It is often the sign of a concealed hemorrhage and is sometimes encountered after the administration of ether or chloroform. Erethistic or delirious shock is said to exist but I do not believe the condition is true shock, but rather a traumatic or toxic delirium added to or following shock. There are also shock from bullet wounds, shock in anesthesia, local shock peculiar to gunshot wounds, shock during operation, shell shock and war shock. The treatment in all these forms is not identical.

In treating ordinary apathetic shock, raise the feet and lower the head, unless cyanosis is caused by such position. The head should be lowered and the body recumbent, maintain body heat, wrap the patient in hot blankets, surround him with hot bottles, hot bricks or hot water bags; always have your bottle, bag or brick wrapped in some material such as flannel, to avoid burning the patient. Stimulants are of little value, when given by stomach. They are not absorbed. Normal salt solution should be infused into a vein, if the blood pressure is below eighty. If the blood pressure is higher give the solution by rectum or subcutaneously. Intravenous infusion is beneficial in hemorrhage. The infusion may be mixed with adrenalin chloride; one teaspoonful of the 1-1,000 solution of the adrenalin chlorid is added to one litre of the salt solution, one half to two pints being given at a temperature of 105° F. or over as it enters the vein. This degree of heat will not damage the corpuscles. If salt solution is given too rapidly or in too great a quantity it may gather in the chambers of the right heart and arrest a heart already weakened. It has been stated that the best way to use adrenalin in severe shock is by Crile's method, to introduce it into the arterial system and toward the heart. Occasionally resuscitation from apparent death may be

accomplished by this means. The technic by this method is as follows: Place the patient in the prone position. He is then subjected at once to rapid, rhythmic pressure upon the chest on each side of the sternum. This pressure produces artificial respiration and a moderate amount or degree of artificial circulation. A cannula is then inserted in the direction of the heart into an artery. Normal salt, Ringer's, or Lock's solution or in their absence sterile water or in the greatest extremity tap water is infused by means of a funnel and rubber tubing. As soon as the flow has begun, the rubber tubing near the cannula is pierced with the needle of the hypodermatic syringe with 1-1,000 adrenalin chloride solution and fifteen to thirty minims are injected. Repeat this injection in a minute if needed. Synchronously with the injection of the adrenalin the rhythmic pressure upon the thorax is increased. The result is an artificial circulation distributing the adrenalin. This causes a stimulating contact with the arteries, bringing a wave of powerful contractions and producing a rising arterial and consequently coronary pressure. When the coronary pressure rises to forty m. m. or more, the heart is likely to resume action. The first result of this action is to spread still further the blood pressure raising adrenalin causing a further rise in blood pressure. Such pressure favors tissue resuscitation especially of the central nervous system. When the heart beat is well established withdraw the cannula because there is no longer need for it. Unless there has been hemorrhage, the only reason for using saline infusion is to introduce adrenalin into the circulation toward the heart. Bandaging the abdomen and extremities tightly over masses of cotton is an excellent addition to this treatment. In prolonged shock and shock accompanied by hemorrhage, direct transfusion of blood is indicated. Hot and stimulating rectal enemata are important agents of treatment also. Enemata of hot coffee or hot normal salt solution are beneficial. In giving such enemata carry the tube as high as possible and inject so as to distend the colon. Another effective method of treatment is hypodermoclysis of normal salt solution into the cellular tissue of the loin, scapular region or under the breast after thorough disinfection of the point of injection with iodine. The syringe holding the salt solution being two or three feet above the bed, a pint or more of the solution will be absorbed in an hour's time. Strychnine, hypodermatically, is of doubtful value in collapse, in fact it may be harmful by increasing the heart action when the heart has not enough blood passing into it to enable it to contract firmly and strongly. Atropine is beneficial in shock, especially if the skin is moist. This drug acts upon the vasomotor system, combats vascular dilatation, maintains vascular tone, opposes blood stagnation and increases the amount

of moving blood. Senn recommended a hypodermic syringeful of sterile camphorated oil every fifteen minutes until reaction begins. Inhalation of oxygen frequently serves well and artificial respiration may be necessary.

Opiates are contraindicated in shock. Mustard plasters over the heart, spine and shins are used. A turpentine enema is useful. Pituitrin is valuable to restore blood pressure. Intramuscular pituitrin injections in ten to thirty minim doses or intravenously in saline solution are often given. In severe cases of shock bandage the extremities. Bandaging for the relief of shock is called auto-transfusion and causes an increased peripheral resistance, enabling the body to utilize to the best advantage the small amount of circulating blood, sending most of it to the brain, where it will activate the vital centres and maintain respiration and circulation. It is well to massage the abdomen also and drive out the blood imprisoned in the splanchnic area, after which a compress and binder are applied to prevent a quick return of the intraabdominal circulation. With very low blood pressure and continued bleeding immediate transfusion of blood is imperative. Artificial respiration and stimulation of the diaphragm may be used with good effect. When death without prompt operation is certain it is proper to operate during shock, the shock itself being treated vigorously by assistants not concerned in the operation.

Treat delayed shock as you do apathetic shock if hemorrhage, sepsis and fat embolism are excluded. If hemorrhage exists, arrest the bleeding and give a blood transfusion or a saline infusion into the vein, using adrenalin as in apathetic shock if the hemorrhage is firmly checked. In delirious shock due to sepsis the treatment is that of the sepsis or if due to uremia, the other most common cause for the so-called delirious shock, the treatment is the same as for uremia. Shock from bullet wounds may result from deeply concealed hemorrhages and calls for treatment.

Local shock from gunshot wounds relates to the devitalization of the tissues in the immediate vicinity of the wounds and the treatment of this condition is to rest in asepsis; it is further stated that "antiseptics will tend to maintain this state of lowered vitality and to favor microbic attack," (1). The hypertonic saline treatment, Sir Almroth Wright's method in gunshot wounds, has many advocates, while some consider it inefficient. For irrigation or immersion a five per cent. solution of sodium chloride, in extremely septic cases a ten per cent. solution is used and when the wound becomes clean normal salt solution is substituted. In a short time this is abandoned and the wound is then merely dressed with gauze moistened in normal saline solution. Free drainage and removal of foreign matter, destroyed tissue and blood clots are necessary. Shock in anesthesia is treated by diminishing the amount of the anesthetic. Atropine is given hypodermically, especially when there is a profuse perspiration. Hot saline by rectum, heat to the body and lowering the head of the bed are all important in treat-

ing shock of anesthesia. The syncope of this condition is caused by a sudden cerebral anemia and calls for lowering the head and giving a hypodermic injection of strychnine. In extreme syncope, more likely to occur from chloroform, suspend the anesthetic entirely, lower the head, open the mouth with a gag, catch the tongue and make rhythmic traction while an assistant is making slow artificial respiration. If no improvement is noted invert the patient completely, holding him by the legs, and continue artificial respiration by compressing the sternum (Nélaton). Atropine, ether or ammonia by hypodermic injection, also mustard to the heart and spine, and faradism to the phrenic nerve are recommended. Fresh air should be admitted into the room. In some cases of anesthetic poisoning direct massage of the heart has been successfully employed. This was first suggested by Schliff in 1874. Hysteria found in men at the front is called war hysteria or war shock. Many writers have called it shell shock, a wrong term because this implies a shock due to shell explosions, an incorrect idea. Yet an explosion may cause a ruptured ear drum and bleeding from the ear. From war shock or shell shock temporary conditions such as deafness, blindness, dumbness, convulsions, forms of paralysis, states not unlike cerebral concussion, symptoms of neuritis, zones of anesthesia, muscular contractures, delirium, mania, tremor and spinal conditions may arise. War shock or shell shock should be treated by a neurologist, not by a surgeon.

Early Surgical Intervention in Severe Sprain of the Knee.—Leriche and Santy (*Lyon médical*, April 25, 1920) maintain that in certain severe sprains of the knee, with some degree of dislocation due to complete tearing of the infrapatellar fibrofacial tissues or with loosening of the crucial ligaments, it is well to intervene surgically as soon as possible in order to repair the tissues before definite retraction has set in. In a recent case, arising through a tramway accident, there was complete dislocation and flaillike condition of the knee joint, together with contusion of the abdomen and injury to the scrotum. Two hours after the accident, the abdomen having been opened and found negative, and the scrotal wound excised and sutured, a U shaped arthrotomy of the knee was performed and a piece of contused skin of the size of the palm of the hand removed. The torn infrapatellar tendon was trimmed with scissors, and likewise a large tear in the lateral fascial tissues. The free, torn portions of the crucial ligaments, the loosened cartilages, and bone fragments from the tibia were removed, and the synovial membrane, capsule and infrapatellar tendon returned. Three days later a few additional sutures were placed in the tendons and the skin wound closed. The patient recovered with a firm knee joint, without dislocation. Ten weeks after operation the patient walked about.

ON THE USE OF BENZYL BENZOATE IN SOME CIRCULATORY CONDITIONS.*

By D. I. MACHT, M. D.,
Baltimore, Md.

In a communication presented in February, 1918, before the Society for Experimental Biology and Medicine, I described my work on the relationship of the chemical structure of some opium alkaloids to their effect on smooth muscle and the discovery of a new therapeutic agent, benzyl benzoate, as a consequence thereof (1). I showed that the peculiar and interesting effects of the opium alkaloid, papaverin, on the tonus and contractions of smooth muscle must be ascribed to the benzyl portion of its molecule and that the same effects, pharmacological and therapeutic, can be produced by the use of a simple benzyl ester. A complete pharmacological and therapeutic study on the subject was published (2). The conditions in which the benzyl effect was anticipated to produce therapeutic results, and in which such results were actually obtained by subsequent clinical trials, were those exhibiting either excessive peristalsis or excessive spasm of plain muscle viscera. Among such conditions were mentioned the following: Excessive peristalsis and colic of the intestines, as, for instance, in diarrhea and dysentery; spasm or colic of ureteral muscle, or renal colic; spasmodic contractions of the gallbladder, or biliary colic; spasmodic contractions of the uterus, or uterine colic; spasmodic contractions of the urinary bladder; spastic constipation, due to powerful tonic contraction of the intestine; pylorospasm; bronchial spasm, and arterial spasm.

I am happy to state that during the two and a half or more years since the first announcement of this work, I have gathered a large amount of additional pharmacological and clinical data concerning benzyl benzoate and that all my original observations have been fully confirmed and the therapeutic results obtained have more than corroborated my most sanguine expectations. In the present paper I wish to call attention to a therapeutic use of benzyl benzoate which I have already described, but which is not so well known as yet to the general practitioner, namely, its employment in the treatment of certain circulatory conditions.

PHARMACOLOGICAL DATA

The action of benzyl benzoate on circulation has already been described. The most striking effect of the drug is exerted upon the vascular system. After injections of benzyl esters, a fall in blood pressure is noted which can be shown to be due to a peripheral vasodilatation, the fall being a result of the depressor action of the drug on the smooth muscle cells of the arterial walls. The effect on the vasomotor centre after ordinary doses is negligible and unimportant. The effect upon the heart itself, after small doses of benzyl benzoate, is negative; so that after injections of the drug there is a marked fall in blood pressure without any depressant effect upon the heart muscle itself. Such an action is well illustrated by the subjoined curve, which shows the effect of an intravenous injection of benzyl benzoate in the form of an emulsion in a dog (Fig. 1). It will be noted that while the pressure had fallen the respiration and the heart beat were not at all impaired. Furthermore, it is interesting to note the long duration of the fall in blood pressure, with the gradual recovery to normal. Even an injection of a small dose of epinephrine was not completely effective in bringing the pressure level back to normal. All that adrenalin did was to cause an immediate sharp rise in the blood pressure, which then fell again and only gradually rose to the original level as the benzyl effect wore out. Even toxic doses of benzyl benzoate have been found by me to produce little effect upon the heart, a fatal dose killing the animal through paralysis of the medulla, and not of the heart.

THERAPEUTIC INDICATIONS.

In view of the marked vasodilator properties of benzyl benzoate, a therapeutic application of the drug naturally suggested itself. The indication for its administration was obviously a spastic contraction of the arteries, or angiospasm; and the drug was given to patients exhibiting such a condition with very satisfactory results. I have collected a large number of data concerning the use of benzyl benzoate in cases of hypertension observed by myself and by many other physicians. The best results, of course, were obtained in cases of idiopathic or essential hypertension, or high blood pressure without demonstrable involvement of the kidneys. The drug, however, was found effective in cases of high blood pressure, irrespective of its etiology,

*From the Pharmacological Laboratory of the Johns Hopkins University.

wherever the arteries were not calcified and were anatomically capable of dilatation.

It was found that benzyl benzoate reduced both systolic and diastolic blood pressures. The following are a few illustrations of the clinical results obtained:

Patient, A. K., blood pressure on examination 212/132. After five days' administration blood pressure was 182/110.

Patient, I. L., blood pressure before, 210/130; after, 180/120.

Patient, M. S., blood pressure before, 194/110; after, 164/98.

Patient, H. M., blood pressure before, 230/120; after, 175/105.

Patient, A., blood pressure before, 315/160; after, 240/148.

Patient, B., blood pressure before, 194/100; after, 178/80.

Patient, C., blood pressure before, 170/98; after, 150/80.

Patient, D., blood pressure before, 212/132; after, 182/110.

Patient, E., blood pressure before, 225/200; after, 165/120.

Patient, R. L., blood pressure on examination 225/200; after administering twenty-five drops of a twenty per cent. solution of benzyl benzoate for two days, the blood pressure fell to 165/140, and by the end of the week it became 165/120; after two weeks the pressure in this patient was reduced to 160/98.

Patient, A. W., blood pressure on examination 220/114; after five days' treatment with benzyl benzoate, twenty per cent. solution, three times a day, the pressure fell to 165/100.

Patient, L. L., blood pressure on examination 194/100; after five days' treatment, 178/80.

COMMENT.

I have found few cases of high blood pressure in which that condition was not relieved, at least temporarily, by benzyl benzoate. Most of the cases treated with the drug were ambulant patients who attended to their daily occupations while taking the drug while all the other conditions were the same. The only difference being the taking of benzyl benzoate, the effect of the drug in reducing the blood pressure was indisputable. In most of the patients the reduction of the blood pressure was accompanied by an improvement in their general condition. Thus, patients who complained of precordial pain or oppression showed decided improvement in that respect.

The most convenient and effective form of administration of the drug was found by the author to be the one originally used in his earlier experiments. A twenty per cent. alcoholic solution of benzyl benzoate was administered by mouth, either in cold water or milk. The ordinary dose was found to be twenty or thirty drops of such a solution, taken three or four times a day. The administration of benzyl benzoate in the form of a solution was found to be especially useful because it allowed of a convenient reduction of the dose whenever desirable. I have found that after administering to a patient full doses of benzyl benzoate and obtaining a desirable therapeutic effect, the reduced pressure could be maintained by keeping a patient on very small doses of the drug, sometimes no more than five minims of the twenty per cent. solution.

The effect of benzyl benzoate on the blood pressure was demonstrable even in such cases in which nitrites failed to produce a vasodilatation. Thus, I have been able to reduce a high blood pressure in patients who have become habituated to nitroglycerin

and sodium nitrite. The onset of the benzyl effect, however, is not as rapid as in the case of nitrites, although sometimes the vasodilator effect was appreciable within thirty minutes. The duration of the benzyl effect, on the other hand, was much longer than that in the case of the nitrites, with the possible exception of erythrol tetranitrate. The blood pressure sometimes remained at a low level for several days after discontinuing the drug.

In my experience no toxic effects have been noted after administration of benzyl benzoate by mouth. The drug has been given to some patients repeatedly for periods of over a year or more, without producing any untoward symptoms. So far as I have been able to ascertain from examinations of urine

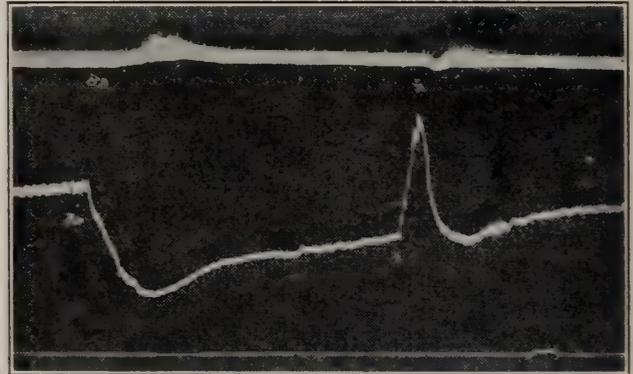

FIG. 1.—Dog, 8 Kilos. Paraldehyde anesthesia. Upper curve shows respiration; middle curve shows blood pressure; lower curve the time in five seconds. At BB, twenty mg. of benzyl benzoate in the form of an emulsion was injected into the femoral vein. At Ep, one mg. of epinephrine solution was injected. Note the fall in blood pressure and the lack of depression in the respiration and heart beat. Note also the prolonged duration of the benzyl effect on the blood pressure, with a gradual return to the normal level.

and functional tests of the kidneys, benzyl benzoate does no harm to the latter organs, and may therefore be administered, if desired, to patients suffering from nephritis.

As in the case of nitrites, however, I have noted, after observations extending over a period of more than two years, that patients will become habituated to benzyl benzoate and will not react as promptly to it as at the beginning of the treatment. Such patients, however, were generally of the nephritic type, whose condition was expected to become aggravated in the course of time.

While benzyl benzoate acts as a vasodilator and will therefore reduce excessively high blood pressure, the indications for its clinical use are precisely the same as for the use of other vasodilators, such as the nitrites. Its action is a purely symptomatic one, that is, in reducing the blood pressure. It is of course well known that a reduction of the blood pressure in many cases of renal disease and other conditions is not indicated and may even be harmful. In such cases, of course, benzyl benzoate is not to be used any more than nitroglycerin or sodium nitrite.

EFFECT ON CORONARY ARTERIES.

I have noted a beneficial effect following the use of benzyl benzoate in patients with hypertension who suffer more or less from precordial pain. I have also given the drug successfully in a few cases

of angina pectoris. If, as is generally supposed, anginal attacks are due to paroxysmal spasm of the coronary arteries, the favorable effects of benzyl benzoate may be explained by its vasodilator action on those vessels. Dr. A. B. Spach, of Chicago, collected a series of such cases, which is published elsewhere, and is of great interest. The pharmacological action of benzyl benzoate certainly warrants a more extensive trial of that drug in the treatment of this condition. The best method of employing it would seem to be to administer it between the acute anginal attacks. For the acute attacks the effect of benzyl benzoate by mouth would be too slow, and in order to relieve the patient it would either have to be given by subcutaneous injection in oil or, still better, the attack should be combated with a whiff of amyl nitrite.

SUMMARY.

Benzyl benzoate has been shown to be a powerful vasodilator, without being depressant to the heart when administered by mouth in small doses.

Owing to this property it has been found effective in the treatment of hypertension and angina pectoris.

The best method of administering the drug in such cases is in alcoholic solution, which admits of rapid absorption and a control of the dose.

NEW THERAPY IN THE LIGHT OF NEW PHYSIOLOGY.

BY JOHN J. McNULTY, M. D.,
New York.

"Medicine needs a new physiology which will teach what health really means, and how it maintains itself under the ordinary varying conditions of environment. We also need a pathology which will teach how health tends to reassert itself under totally abnormal conditions, and a pharmacology which will teach us not merely the actions of drugs, but how drugs can be used rationally to aid the body in the maintenance and reestablishment of health. The new physiology, new pathology, and new pharmacology are growing up around us just now."—J. S. Haldane.

In clinical medicine we can be guided in our service by the larger, more inclusive vision. As helpful physicians we must consider the whole rather than the mere local aspect. If we are to serve in a social complex we must serve as those who have caught glimpses, at least, of a new biology, a new physiology, a new therapy. Let us hear and let us hold one thematic note, the note of the rhythm of the normal. Until we think the rhythm, hear the rhythm, see the rhythm of the normal we are unfit to enter into the presence of biology. The ineffectiveness of past therapy and much present therapy is the result of ignorant interference with Nature's law of maintenance and her law of repair. There is a beneficent, a helpful cooperation the physician can offer if he has caught a glimpse of Nature's law.

We are on the threshold of fuller revelation; a clearing away of the mist of false concepts. We seem to be ready for a higher understanding of that which appears ready to reveal itself; a vision of truer perspective. Man is too delicately adjusted in his physiology, in his interrelations and interdependencies of function, for the unskilled to meddle with this delicate adjustment. As we see more clearly the phenomenon of human life, we begin to perceive how wonderfully and fearfully this organism is made in its interrelated and interdependent functioning. Sensitive adjustment is a requisite of its continuance. The uninformed should not tamper with it.

It now appears as though the normal of physical man is dependent largely for its rhythm upon the functioning of the so-called autoprotective mechanism—the endocrine chain or cycle—an internal organism whose intelligence so transcendently surpasses our cerebral intelligence that it endeavors to protect itself against unskilled interference. This autoprotective mechanism stands only partly revealed, but now enough understood in its character and activities that we may approach it interrogatively and ask if we can aid in conditions of embarrassment.

Insufficiencies and sometimes deficiencies in this endocrine cycle seem to be a cause of modification of function and disorder of physiological rhythm. In this line of research there seems to be a real reason to feel that we can often come to Nature's aid through contributing from without substances like those which are insufficient or deficient. These substances—ductless gland substances—when administered, find their place of selection and by their presence, as catalysts, awaken, activate the inherent, the resident reaction. We have been so awkward, so clumsy in our use of endocrine substances in endocrine therapy, in thinking that gland substances owe their efficacy to volume and stimulation rather than understanding that internal secretions and enzymes aid only through the properties of vital catalysis to maintain a more normal "concentration and velocity of reaction."

A wonderful cycle of activities is the so-called endocrine system. The rhythm of the normal is delicately sensitive, notwithstanding a toxic environment. It is probable that the first deviation from the normal and its rhythm is due to a fatigue of the glandular system, especially the suprarenal glands—suprarenal fag; for the suprarenals seem to have most of the work to do in the autoprotective mechanism. We do not understand enough as yet of the endocrines to say which is the initiative, which is the receptive centre that receives and directs, but the suprarenal function seems to have no rest.

"Costa stated that nice distinctions between conditions due to various ductless gland disorders are very difficult to make. He does not attempt the differentiation suggested by Claude and Gougerot and others to determine in which gland the hypo-function (or hyperfunction) predominates, and which is essentially responsible for the disturbance. This undertaking appears to him much too difficult at present," states Luciani.

We are commencing to perceive enough of new physiology to know that the endocrines are vitally interrelated and interdependent in a unified function. With increasing knowledge of how the endocrines are interrelated and interdependent, we are not justified in a hazardous adventure of thinking we know, from obvious symptoms, which gland is primarily affected, and upon this evidence administer a seemingly indicated single gland substance.

Until our knowledge of the endocrines—their relations and reactions—becomes much clearer and more complete, we should administer small quantities of associated gland substances as they seem to be associated and act in the living human organism. Haldane stated: "A living organism differs in this respect from any mechanism which we can construct or conceive, that it forms itself and keeps itself in working order and activity." This is what new therapy should seek to do to aid an embarrassed living organism to form itself and keep itself in working order and activity. This is all the new therapist intelligently desires or attempts to do. We hope the old superficial and harmful interference with the living organism's selfworking is rapidly passing in the light of new physiology and new therapy. Again referring to Haldane: "Stated generally, therefore, the problem of physiology is not to obtain piecemeal physicochemical explanations of physiological processes, but to discover by observation and experiment the relation to one another of all the details of structure and activity in each organism as expressions of its nature as an organism.

"What is the practical object of medicine? It is to promote the maintenance and assist in the reestablishment of health. But what is health? Surely it is what is normal for an organism. By normal is meant, not what is the average, but what is the normal in the biological sense—the condition in which the organism is maintaining in integrity all the interconnected normals which . . . manifest themselves in both bodily structure and bodily activities."

In the light we now have to work in we can aid in the maintenance and assist in the reestablishment of health. The physician equipped with the new physiology and new therapy can abstain from stigmatizing his patient with incurable terms, for he knows with a clearer understanding that he can aid in the reestablishment of the normal, the normal with its rhythm. He can approach the embarrassed organism which manifests faulty functioning and, with a scientific understanding of qualitative and quantitative endocrine therapy, aid in the reform of conditions which have been considered incurable.

Endocrine therapy, and by endocrine therapy we mean associated gland substances, is not a wand we can credulously pass over the afflicted and say, Presto change. Associated gland therapy is a progressive, an improved effort to scientifically assist the organism manifesting weariness or even disease.

It is the holding of the physiologically normal in thought that protects us and our patients from errors in prognosis. The physician who today is serviceable in his socioprofessional relations is the practical physiological therapist who holds in thought the physiologically normal; the rhythm of the nor-

mal even in the face of the powerful influence of old pathological concepts. The physician who thinks and acts only in terms of pathology is today unacceptable. I have been approached by old patients who state that twenty years or more ago I was called to see them in uremic coma, that examination of the urine showed large hyaline casts, and still further informed that they had enjoyed twenty or more years of health with efficiency. I have answered that I hoped I would never again condemn with terms of fatality, for I now knew somewhat of Nature's law of repair; we should understandingly cooperate with this law of reestablishment. Most physicians desire and try to help but in their effort, guided by old therapy, they add embarrassment to embarrassment. New physiology and new therapy direct our desires and efforts more wisely, more serviceably, more reparably.

"But medicine, as we have seen, is supremely interested in the physiological normal. What a man sees at the bedside is a perversion of the normal, and Nature's attempts to restore it with what assistance medicine can give. For medicine it is necessary to know the normal in its elastic and active organization," states Haldane. "Old therapy is often so helpless. New therapy does not, like the old, seek to interfere but with a new understanding cooperates effectively with Nature in her law of return to the normal—to elastic and active organization.

Let us here state that if the full benefits of endocrine therapy are to be obtained the care of the entire organism must be considered. Rhythm of the normal; let us think it, see it, hear it and, as physicians, cooperate with it.

The time is now here when the intelligence of the so-called laity will not tolerate the physician who is only thinking in terms of pathology and its gruesome cortège of fatal terms. Society today needs the new physiologist, the new therapist who, to some working degree, understands the constant endeavor of the organism to maintain the normal rhythm. We find this reflected in Haldane: "My intellectual as well as my moral sympathies are all with the cheery general practitioner whose moral is 'Never say die.' and who flashes defiance at this dismal ghost."

". . . biological conception of organic regulation"—this is our theme, and this our desire. May we more fully understand it and more helpfully cooperate with it as general practitioners and as broadly equipped endocrinologists. "To whatever part of physiology one turns one finds evidence accumulating of the fineness and omnipresence of organic regulation." Let us work with this "fineness of organic regulation." "Treatment can only be securely founded on the correct and full diagnosis of what is amiss in organic regulation, and how nature can be aided in restoring this regulation."

The men who have blazed a trail in the wilderness of the unknown are those who have contributed the greatest blessings to afflicted humanity.

In endocrine therapy the temptation may come to see only the obvious, and treat only the obvious. This is the origin of monoglandular therapy. The one gland therapist does not understand that thyroid imbalance, hyperthyroidism or hypothyroidism, is rarely if ever a primary thyroid disorder. It may

be and usually is an objectification of suprarenal, or pituitary, or gonadal primary disorder or disease. This is why associated gland therapy is not only more scientific but more efficacious than single gland therapy. The law that the associated gland therapist works with is the organism's law of accurate, intelligent selection; selecting what is insufficient or deficient and appropriating it. Until our knowledge of physiology more clearly and perfectly approaches the intelligent selection of the autonomic mechanism, organic regulation, we should administer internal secretions and enzymes in associations, associated as they seem to be associated and act in the living human organism, confident that the resident intelligence will select needed supplies wisely.

I desire to quote here a paragraph from one of my former articles: Internal Secretions and Enzymes, Their Interrelation and Interdependence, Their Value and Application in Modern Therapy:

"Physiologically associated internal secretions and enzymes, endocrine therapy, has created a new therapeutic era. We can now treat disorders that we formerly and even recently called incurable, with greater confidence. No physician with present day understanding should allow a fatal prognosis to take possession of his thought nor should he voice a fatal prognosis. We now have sufficient understanding of a fixed and certain biological principle to apply it in curative therapy. The dawn is appearing over the domain of biological phenomena and we are beginning to understand their influences and utilize them beneficently. The old idea of the futility of treating so-called incurable diseases is rapidly giving place to definite and competent therapy based on successful issue."

We desire to quote the following from a recent article by Dr. S. W. Bandler:

"New things are always treated with scepticism, but each thinking physician may observe in his practice abundant material for research. By working together we may soon prove beyond doubt that while heredity shapes our ends there is an endocrinity that runs parallel."

New therapy based on new physiology is an improved therapy, a therapy that obtains results unlooked for in old methods of treatment.

THE EARLY SIGNS OF TABES.

By BURTON PETER THOM, M. D.,
New York,

Visiting Syphilologist to the Hospitals of the Department of Correction, Blackwell's Island.

With the exception of paresis, the most desperate symptom complex of which the spirochetal invasion of the nervous system is the cause, is tabes. Paresis is the same pathological manifestation as tabes only at a higher level; paresis involves the brain, whereas tabes involves the cord. It can therefore be asserted that every tabetic is a potential paretic. Until quite recently tabes could not be cured, its progress stayed or its symptoms mitigated except by the relief which opium affords. This was due to wrong

conceptions of its pathology but more especially to inadequate methods of treatment. But since the discovery of the *Spirochæta pallida*, the Wassermann reaction and the advent of salvarsan all this is changed and now this dread disease, like many others, if attacked in its earliest stages is amenable to treatment. For, if it cannot be cured as some still believe—I am not among the number—its morbid processes can at least be stopped and its victim saved from its impending terrors.

Unfortunately, however, most of those suffering with tabes when they resort to the neurologist or syphilologist have reached the stage when such help cannot be given or only to a slight degree. Of these, many, I regret to say, are so because of faulty or careless diagnosis. If a correct diagnosis had been made at the beginning this melancholy procession would not be, or perhaps I had better say, it would not be so long.

The proper time to treat tabes is before it starts. This may seem a paradox but no more so than the ancient saw that "an ounce of prevention is worth a pound of cure." The importance of this statement I cannot emphasize too strongly and I will give reasons why it cannot be denied. It is well known that the *Spirochæta pallida* in common with all trypanosomes has a decided predilection for nervous tissue; and further, this predilection is in evidence at the very commencement of its onslaught. The researches of Dreyfus, Leishman, Ravaut, Fordyce and many others present ample testimony of this. They have shown that the specific reaction of lues is present in the spinal fluid of from twenty to thirty-five per cent. of all the syphilitics examined by them in the first year of the disease. If we strike an average of the percentages noted by the various observers it can be assumed that fully one fourth of all syphilitics in the first year of the disease show an invasion of the cerebrospinal axis. This invasion is independent of any nervous lesion being manifest. Be this as it may, it cannot be denied that any individual with a positive Wassermann in the spinal fluid is perforce a candidate for nervous syphilis. We also know with equal certainty that in nothing like twenty to thirty-five per cent. of syphilitics cerebral or spinal syphilis develops. It must therefore follow that the major portion of the potential neural syphilitics either get well spontaneously or as the result of treatment. But it is also true that a definite percentage do not resolve in this manner and nervous lesions follow early or late. It is variously estimated that in from fifteen to twenty per cent. of syphilitics who acquire the disease tertiary symptoms develop. In approximately one third of these the nervous system is involved. Tabes is by far the most prevalent form.

Since we know that the seeds of the disease are sown many years before, it must follow if they are not allowed to grow, tabes, and for that matter, all other syphilitic nervous diseases, can in most instances be prevented. Knowing this no case of syphilis in the early cycle of its development should be pronounced cured until a lumbar puncture had been made and the spinal fluid found to be normal. This should be in addition to repeated negative findings in the blood. Should the spinal fluid be

positive, even if the blood is negative, which not infrequently happens, energetic intraspinal treatment should at once be instituted and kept up until the findings in the spinal fluid have returned normal. This procedure should admit of no exception if we are to insure our patients, as far as is humanly possible in our present state of knowledge, against the future raid of the spirochetæ upon the nervous system. If this were made an inflexible rule in every case of early syphilis, tabes as a disease entity would almost disappear, or at least be lowered to the irreducible minimum common to all preventable diseases.

I realize that it is not always possible to control every case of early syphilis in the manner just described. Also, the majority of tabetics do not present themselves until well marked symptoms are present. It is not my purpose here to discuss these cases but rather those in which the subjective and objective symptoms are just beginning and in which the element of doubt as to the diagnosis of the condition still exists in the mind of the physician. There are many such and if their malady is diagnosed correctly they would be spared much suffering. Tabes, like its congener, paresis, is an insidious disease. It is therefore most difficult to diagnose at the onset but it is at this period when the damage done is still slight that it offers the best—I may say the only—opportunity for arrest.

One of the first of the premonitory symptoms of tabes is impotence. Many times it is this loss of sexual power that causes the patient to first seek medical advice. This sexual decadence is never sudden. The patient usually states that he has been noticing a decrease of sexual power for a year or more. If it is found that in conjunction with the impotence the testicles are insensible to pain when compressed it is almost certain that it is due to beginning tabes.

Another early symptom of tabes is slowness in emptying the bladder. In many instances if the patient has ever had gonorrhœa he may consult the physician for what he thinks is a stricture. In these cases there is always a lack of sensibility of the bladder, which may contain a large amount of urine without the patient being at all aware of it. Should the urine show evidences of decomposition, which will be shown by its odor and appearance, a low grade of fever will almost invariably be present due to absorption and a possibly existing pyelonephritis.

According to Osler ten per cent. of all tabetics have the ocular form of the disease; that is amaurosis caused by atrophy of the optic nerve. Failing vision, therefore, which cannot be helped by glasses, or the gradual or sudden appearance of scotoma, central, homonymous or heteronymous, should always cause suspicion of beginning tabes. An ophthalmoscopic examination should be made at once to determine the presence of choked disc; although as Hughling Jackson observed long ago there may be considerable choking of the disc without impairment of vision. Choked disc is not always due to tabes, however; atrophy of the optic nerve from pressure due to a pachymeningitis in the vicinity of the optic chiasm, neuritis of the nerve, an embolism of the lenticulate artery or an aneurysm of the same, a thrombus of the central retinal vein,

or glaucoma must also be considered. Smallness of the pupils—spinal myosis—may precede the classic Argyll-Robertson pupils for a considerable period and this condition of the eyes should always arouse suspicion. Diplopia or double vision is sometimes encountered in early tabes, as well as the slow and painless development of paralysis of the external muscles of the eye. Moebius is of the opinion that these symptoms are as significant of tabes as the Argyll-Robertson pupil.

A symptom which is highly suggestive of beginning tabes is loss of bone conductivity as exemplified by Egger's test with the tuning fork. It is not infrequently the very first objective symptom of the disease. Sudden deafness, a condition which has been compared by Hermet with primary optic atrophy, is also a sign of beginning tabes. Sudden or gradual loss of hearing in a middle aged man where no other cause can be assigned should cause a suspicion of tabes.

The so-called lightning pains which are present in the early as well as the later stages of the disease are very often mistaken for rheumatism or sciatica. To treat them as such, as so often happens, is to lose much precious time. There are certain peculiarities about the pains of tabes which should give pause before they are lightly dismissed as due to sciatica or rheumatism. One is the intensity of the pains. The pains of rheumatic arthritis or sciatica cannot possibly compare with these agonizing flashes which come and go with the rapidity of lightning—hence their name. Rheumatic pains, if of the muscles, are diffuse and if of the joints, as they usually are, there is stiffness. There is no stiffness of the joints in incipient tabes. Sciatica is often extremely painful but the pain is constant, it does not come and go as in tabes. It may be so severe as to cause the patient to limp, but it is never as intense as the shooting pains of tabes. It follows a definite tract—the course of the sciatic nerve. The pains of tabes are not definite in so far as any particular nerve distribution is concerned. When they leave, the skin over where the pains have been is sore and tender to the touch for some time after. As pointed out by Strauss, spots of purpura not infrequently follow these attacks over where the pains have been. Sometimes there is a herpetiform eruption not unlike that observed in shingles.

Loss of the patellar reflex is one of the early signs of tabes. For many years it may be the only objective sign of the disease. With loss of the patellar reflex it will almost invariably be noted that the triceps reflex is also absent. In examining for loss of reflexes however, I desire to call the reader's attention to the fact that the first reflex to be lost is that of the tendo achillis—the ankle reflex. In determining the presence or absence of the reflexes, most examiners test the patella or knee reflex first and if it is present, in many instances the possibility of tabes is dismissed. This is wrong. The first reflex to be tested should be that which is the first to disappear and that is the ankle reflex. This reflex is determined by placing the patient in a kneeling position and lightly tapping the Achilles tendon.

The so-called crises, gastric, vesical or laryngeal,

are sometimes present in the beginning of the disease. Usually, however, they do not occur until it is well established and the diagnosis is certain. A sudden attack of indigestion, especially if the patient complains of a peculiar feeling of weight in the epigastrium, or a sudden attack of diarrhea where there has been in neither instance no dietary indiscretion and which persists for several days should always cause tabes to be considered.

Perforating ulcers of the soles of the feet are usually late manifestations of the disease but occasionally they occur as a premonitory sign. I can recall a case in which this condition was present for a number of years before ataxia developed. The same is true of the so-called Charcot's joint—usually a late sign but sometimes appearing early.

A feature of tabes not often mentioned in the textbooks is the frequent presence of cardiac lesions, although attention was called to this thirty years ago by Strümpell. All forms of cardiopathies are to be noted but it would seem that aortic lesions predominate. This is not strange, however, when we consider that aortic disease is almost invariably caused by syphilis. So frequently are cardiac lesions coexistent with tabes that their presence where rheumatism or endocarditis can be excluded should always cause a search for the incipient signs of tabes.

Any individual in whom tabes is suspected should have a Wassermann test of the blood and of the spinal fluid. A cell count and the globulin reaction and the reducing power for Fehling's solution should also be ascertained of the spinal fluid. The colloidal gold test to show the tabetic curve can, in my opinion, be ignored. If present, it of course helps to confirm the other findings. These two examinations should be made even if there is no history of syphilis. For, as every syphilologist well knows, the disease may be present in the blood and spinal fluid and yet be otherwise asymptomatic. The absence of scars due to gross external lesions should not deter the examiner, for in the majority of instances they are not present. Should the blood be returned negative it does not by any means follow that the physician's suspicions are incorrect. It has been said that one swallow does not make a summer, neither does a single negative Wassermann reaction preclude syphilis. The blood is not infrequently negative in tabes and yet the disease may be present. Several tests should be made and if a doubt still exists a provocative salvarsan injection should be given and the blood tested repeatedly thereafter for at least ten days.

The cytological findings, however, are by far the most important. For, while syphilis may not be manifest serologically it will invariably give indications of its presence in the spinal fluid. I desire to emphasize this because it has been asserted and is quite generally believed that the Wassermann is negative in approximately fifty per cent. of tabetic spinal fluids. In spite of its wide circulation this statement in my opinion is incorrect. The reason for this seemingly large number of negative findings in tabes is due to the fact that too small an amount of fluid is used in making the test. If instead of two tenths c. c. of fluid, three or four c. c. were used the Wassermann would be found positive as

often as in paresis, i. e., one hundred per cent. The cell count in early tabes is always increased which is indicative of a more or less acute process. It is only when the disease is in a state of arrest or has progressed so far that the nerve tracts are completely destroyed that the cell count sinks to normal or nearly so, that is to ten or twelve cells to the counting chamber. The fluid also usually flows out under pressure. The globulin index is increased and there is reduction of Fehling's solution.

It is not my purpose here to discuss the treatment of tabes in this early stage. I believe treatment—salvarsan intravenously and intraspinaly—will arrest and in not a few instances cure the disease at this stage. One thing at least is certain; this early stage is the only stage where treatment offers such a hope. It is the patient's hour of fate—his only opportunity, and it is the duty of his physician to grasp it boldly and try to save him from what means eventually, as expressed by Heine, a "mattress grave."

1632 AVENUE A.

ADMINISTRATION OF SALVARSAN BY RECTUM IN THE FORM OF ENTEROCLYSIS.*

Preliminary Report.

BY V. WILLIAM M. WRIGHT, M. D.,

Philadelphia.

Philadelphia General Hospital.

During my service in the venereal wards of the Philadelphia General Hospital under Dr. Siter and Dr. Alexander Randall, I had occasion to treat syphilitic patients who for various reasons could not be given salvarsan intravenously. It was essential that they receive it in some way or other as mercury and the iodides were inadequate. Realizing that they would be benefited by it if they could get it I decided to find some way. Textbooks and journals were searched for other methods, but those given did not seem satisfactory and uniformly safe.

In Warbasse's *Surgery* there appears the following statement: "The patient comes to the operation empty, hungry, and thirsty. The patient lies on his right side; an adult is given morphine, a child paregoric." With this as a nucleus salvarsan by enteroclysis was begun.

Following the basic principles that the patient should be empty, thirsty, and hungry, the patient was made empty and hungry by starvation and purgation and thirsty by withholding liquids and giving a few doses of atropine. In a series of fifty cases the following routine was followed:

If the administration was to take place at 1:30 p. m. the patient was given a very light supper, one fluid ounce of a saturated solution of magnesium sulphate and one or two compound cathartic pills at 5 or 6 p. m. of the preceding day. The next morning they were denied the regular breakfast but were given two cups of black coffee and one piece of soft toast. At 7 a. m. they received 1/150 gr.

*Read before the Blockley Medical Society, February 2, 1920, and February 23, 1920 (by invitation) before the Genitourinary Society, Philadelphia.

of atropine, at 10 a. m. another, and went to bed where they remained until that evening or next morning. At 1 p. m. they were given one quarter grain of morphine and 1/150 grain atropine hypodermically. During the entire day they were denied liquids, except in some instances a half glass of milk at noon. At 1 p. m. a "1-2-3" enema was given, consisting of magnesium sulphate one ounce, glycerine two ounces and hot water. By this time the condition of the patient was such that the absorption of the enteroclysis by a dried up bowel was an easy matter,—this is what we wished to accomplish. At 1:30 p. m. the enteroclysis was given and continued at a rate of forty-five to fifty-five drops a minute.

The solutions used varied according to whether salvarsan or arsenobenzol, neosalvarsan or neoarsenobenzol was given. If arsenobenzol was used it was prepared as usual and diluted with hot normal saline to 260-320 c. c. and the enteroclysis bag kept hot by hot water bags or electrical appliances. The neoarsenobenzol was dissolved in sixty c. c. of water at room temperature and diluted to 200-260 c. c. with normal saline and required no heat. As stated, the rate of flow ran from forty-five to fifty-five drops a minute and generally required one and a half to two hours. At first the patients were not al-

55 gtt. per min..	0	55	1	3	1	10

lowed to eat any supper that night, but later it was found that some could eat a light lunch and experience no after effects; those who could not went without food. That night they were allowed a few liquids and the following morning they resumed ordinary conditions and diet.

The untoward effects have been negligible and only once has anything unusual occurred, except now and then slight headache. If the patient cheats on the fasting she is likely to have nausea, perhaps vomiting and headache. One patient was given the enteroclysis with only a preliminary enema and morphine and atropine. That night she experienced pain across the abdomen, diarrhea, painful defecation and nausea. Bismuth, opium, plenty of water, rest in bed and liquid diet with several enemata benefitted the patient. There were no later manifestations. Another patient complained of dizziness, and a silly feeling which were traced out as an idiosyncrasy to atropine and morphine.

The dose varies between 0.6 gram and 0.9 gram. Nearly all were started with 0.6 gram of arsenobenzol for the first one, two or three doses, which was increased to 0.9 gram as the treatment progressed. With neoarsenobenzol 0.9 gram was given for four or five doses and then 1.0 gram. Of course it is not presumed that salvarsan by this method is any more beneficial than when administered in other ways and mercury and iodides are to be used in exactly the same way as in treating syphilis by the intravenous injections of salvarsan.

Indications for rectal administration are as follows:

1. Fat patients with small or no visible superficial veins.
2. Scrawny patients with poor veins.
3. Children.
4. Women for whom needlemarks in the arm would prove inconvenient in evening dress.
5. Patients with knotted veins from previous intravenous injections.
6. Hysterical and highly nervous types of patients.

REMARKS.

1. It is thought that by this method the solution is picked up by the blood vessels and lymphatics of the rectum and sigmoid and the greater proportion of the solution conveyed directly to the liver whence it is meted out, and that much more salvarsan enters the liver and is stored there by this method than by the intravenous method.

2. It has been questioned whether atropine should be used. The method, however, has proved successful in the presence of atropine, the drug which the researches of Novi have proved to be of greatest avail in the prophylaxis of nitritoid shock.

3. Morphine tends to quiet the patient and put him in a mental and physical state of acquiescence. This is especially helpful in the case of excitable and hysterical women, in whom an extra injection of morphine is frequently indicated.

4. The saturated solution of magnesium sulphate given by mouth has a hydragogue action, and desiccates the patient as well as cleansing out the gastrointestinal tract.

5. Any preparation of arspenamine or neoarsphenamine lends itself readily to this method of administration. In our hands, however, the neoarsphenamine has given the better results. It is less toxic and far less troublesome to prepare and administer.

6. More concentrated solutions might be used, but the above dilution has proved entirely satisfactory.

7. Critics prejudiced in favor of the intravenous administration of these drugs have raised the objection that much of the dose might be ejected by defecation. They fail to taken into consideration the fact that owing to the large doses of atropine and morphine given, with the resulting bowel atony and inhibition of peristalsis, there will be no bowel movement for many hours. During this interval

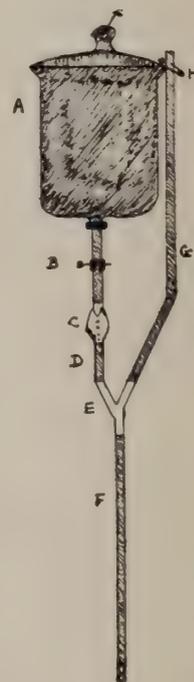

FIG. 1.—A. Hot water bottle or glass container. B. Dropcock. C. Murphy dropper. E. Glass Y. F. 20 French rubber catheter. G. Gas pressure release. H. Safety pin.

Dr. Morrison's apparatus for enteroclysis. (Modified by the Author.)

When no escape tube is used, gas forming can find no outlet owing to the construction of the single tube by the dropcock. The rectal catheter is therefore expelled by the intrarectal pressure. The same is prone to occur if the rate of flow is too fast and no adequate bypass is provided. This difficulty is entirely obviated by the use of the glass Y and escape tube featured in the above diagram.

ample time is afforded for the slow and complete absorption of all the drug administered. On the other hand, it is well known that a fair proportion of the dose of these drugs administered intravenously is excreted during the first few hours by the kidneys. As yet there has been no time for the laboratory study of the excretions after the administration of salvarsan by rectum. But it would seem that by this method the kidney waste should be reduced. For, when a given dose of arsenobenzol is injected directly into the blood stream the concentration in the blood rises immediately to above its kidney threshold value, and is only reduced to below this value after the liver has had time to effect a balance between storage and circulation. Meanwhile much of the drug has been lost by the kidney excretion. In injections by rectum absorption is slow, and the absorbed product passes directly to the liver, so that the latter is probably able to effect the balance between the storage and circulation before the concentration of the drug in the blood ever reaches the kidney threshold. For this reason the kidney threshold is probably never exceeded in the blood and none of the drug is lost in the urine.

CONCLUSION.

Inasmuch as we have been able to clear up or modify the secondary stages of syphilis and the reaction of the patients' blood to the Wassermann test by the rectal administration of salvarsan in the form of enteroclysis, without the use of mercury or iodides, we believe this to be a satisfactory method for its administration to those who are in need of it and who cannot receive it intravenously.

SEVEN GENERATIONS OF PHYSICIANS.

BY GEORGE SCHUYLER BANGERT, Ph. G., M. D.,
East Orange, N. J.,

Late Acting Assistant Surgeon U. S. P. H. S.; Assistant Surgeon
U. S. P. H. S. (Reserve); Officers' Reserve Corps; U. S. Army;
Member New Jersey Historical Society.

An interesting family leaning towards medicine is shown in the Shippen family. In the first generation appears the name of Edward Shippen, M. A., M. D., the son of Rev. Robert Shippen, B. A., M. A., D. D., and a nephew of Edward Shippen (first mayor of Philadelphia), and a brother of Downright William Shippen, B. A., LL. B., M. P., and a brother of Rev. Robert Shippen, B. A., M. A., D. D. (vice chancellor of Oxford). He was born in Methley, England, in 1671 and married Frances Leigh, daughter of Peter Leigh of Lynne. He received his degrees from Brasenose College, Oxford, and subsequently succeeded his brother Robert as professor of music at Gresham College. He was also a physician.

In the second generation we find the name of Dr. William Shippen, Sr. (member of Continental Congress). He was the son of Joseph Shippen and Abigail Gross, and a grandson of Edward Shippen (first mayor of Philadelphia). (There is an India ink sketch of him by Mrs. Frances B. Pierce in the possession of the Pennsylvania Historical Society, Philadelphia, together with an etching of the same by Albert Rosenthal, 1884.) He was born in Phila-

delphia October 1, 1712. He applied himself early in life to the study of medicine for which he had a remarkable genius, possessing that instinctive knowledge of diseases which cannot be acquired from books. He seems to have inherited his father's eager desire to explore the domains of physical science and no doubt the Junto (American Philosophical Society) had its influence in shaping his course in life. It is not known what university granted him his M. D., but it is thought that he received his early training under one of the Welsh *Chirurgeons* who were brought to this country by William Penn. He received his literary education and medical instruction in Philadelphia where he studied with Dr. Cadwalader and under Dr. John Kearsley, Jr. He was a colleague of Dr. Zachary. Upon Dr. Cadwalader's return from Europe, 1730, he made dissections and demonstrations for the instruction of Dr. William Shippen, Sr. These instructions were given in the building where the bank of Pennsylvania stood in 1809. In 1903 the United States bonded warehouse was built there. It is on the west side of Second Street above Walnut Street.

Dr. Shippen is recorded as being, besides a physician, a chemist and an apothecary. (1) He speedily obtained a large and lucrative practice which he maintained throughout a long and respected life. He was especially liberal towards the poor and not only gave his professional aid and medicines without charge but often assisted with donations from his purse. He was very successful in his practice but did not by any means think that medicine was advanced to perfection. It is said when he was congratulated by someone on the number of cures he effected and the few patients he lost, he said, "My friends, nature does a great deal and the grave covers up our mistakes." Because he was conscious of the deficiencies of medical education in America and was animated by a patient desire to remedy them Dr. Shippen trained his son William, Jr., and sent him to the University of Edinburgh, where he had every opportunity to obtain a knowledge of the various branches of medicine. On his return, May 1678, he commenced a series of lectures on anatomy in one of the large rooms of the State House and thus was begun the first medical school in America (University of Pennsylvania). Dr. William Shippen, Sr., was not much interested in politics but at the close of 1778 when the outlook for the Americans was very dark he was called upon to take part in the convention of the nation. On November 16, 1778 (2) he was elected to the Continental Congress by the Assembly of Pennsylvania by a vote of twenty-seven. He was elected to a second term November 13, 1779. Throughout both terms he was constant in his attendance (3). His advanced years and his professional duties would have furnished ample excuse to a less patriotic citizen for declining the thankless position. Dr. Shippen was always at his post and his vote was that of an honest, intelligent, highminded, patriotic gentleman who thought always of his country's welfare. Dr. Shippen took an earnest part in the Junto from which probably sprang the American Philosophical Society. He was elected to this society, November, 1767, and was

made vice-president 1768-9, and was a member for many years. He was elected physician to the Pennsylvania Hospital for twenty-five years from 1753-1778. He was one of the five prominent physicians serving on the board of trustees from 1755-79.

He was also one of the trustees of the Academy in 1749. He helped found the Second Presbyterian Church of Philadelphia, 1742, and was a member of it for nearly sixty years. He was one of the founders and for thirty years a trustee of the College of New Jersey (Princeton). (One of the stained windows at that University contains the Shippen coat of arms.) He possessed a powerful frame and vigorous health for which his race was noted. At the age of ninety he rode horseback from Germantown to Philadelphia in the coldest weather without an overcoat; and but a short time before his death he took a walk of six miles from Germantown to his son's house in Philadelphia. His mode of living was simple and unostentatious. His temperament was so very serene and forbearing that tradition says: "It was never ruffled." His benevolence was without stint.

He was married in Philadelphia, September 19, 1735, to Susanna Harrison, the eldest daughter of Joseph Harrison and Catherine Noble of Philadelphia. She was the granddaughter of John Harrison and his wife, Mary. Dr. Shippen lived beloved and on November 4, 1801, in Germantown, Pa., at the age of ninety bowed his head, regretted and lamented, and was buried in the graveyard of the church to which he had been so useful in Philadelphia. His summer home which he built in Oxford Furnace, N. J., about 1742, is still standing well preserved. Dr. Shippen owned 10,000 acres of land in what is now Sussex and Warren counties, N. J.

In the third generation we find two brothers, both sons of Dr. William Shippen, Sr., and Susanna Harrison, i. e., Dr. William Shippen, Jr., and Dr. John Shippen. Dr. John Shippen, A. B., A. M., M. D., was born in Philadelphia, Pa., January 23, 1740. He was a graduate of the College of New Jersey, 1758; studied with his father and at the Medical Department of the University of Rheims, France. He received the degree of M. D. there. On his return to America, April 5, 1770, he began a course of lectures on fossils. He died unmarried in Baltimore, Md., November 26, 1770. Dr. William Shippen, Jr., B. A., M. A., M. D., the father of scholastic medicine in America, was surgeon general of the United States during the Revolution and the first professor of anatomy in America and the founder of the first medical school in America, i. e., the University of Pennsylvania.

Dr. William Shippen, Jr., was born in Philadelphia December 21, 1736, and died in Germantown, Pa., July 11, 1808. He was married in London, England, to Alice Lee of Virginia, daughter of Col. Thomas Lee, Governor of Virginia. Dr. Shippen was one of the founders of the first medical school in America, the University of Pennsylvania. He delivered the first course of lectures in America on anatomy November 16, 1762, and was mobbed by the public when he first introduced dissection. He continued to lecture on anatomy and obstetrics until

December 23, 1765. He was elected professor of anatomy and surgery in the Medical School College of Philadelphia, September 23, 1765. He was chief physician of the Flying Camp during the Revolution. He laid before Congress a plan for the organization of the Medical Department which with some modifications was adopted. On April 11, 1777, he was unanimously elected director general of all the military hospitals of the United States army.

He was president of the University of Pennsylvania, Medical Department, from 1805 until his death. He was a graduate of the College of New Jersey and valedictorian of the class of 1754. From that institution he received the degrees A. B., M. A. and received his M. D. from the University of Edinburgh, class 1761. He studied under Senac, John Hunter, McKenzie, and Smellie. After studying in Europe he returned to America, 1762. He was a member of the American Philosophical Society, also one of the first physicians appointed to the Philadelphia Hospital. A eulogy on Dr. Shippen was delivered by request by C. Wistar as an introductory lecture to the medical class in the autumn of 1808 (Portfolio Third Series, Vol. 1, No. 2, February, 1813). He was noted for his graceful personality, polite manners, power of conversation, sociability, conciliatory nature.

He reviewed a lecture not by interrogation but by recapitulation. His portrait by Gilbert Stuart is in Corcoran Art Gallery, Washington, D. C., one in Independence Hall, Philadelphia, one at the University of Pennsylvania and one at the Pennsylvania Historical Society.

In the fourth generation we find Edward Shippen, A. B., M. D., a son of the Chief Justice, Edward Shippen, and Margaret Francis, and a brother of Peggy Shippen, who married Major General Arnold while an officer in the American army. Dr. Shippen was born in Philadelphia, December 11, 1758, and died in Burlington, N. J., October 22, 1809. He married Elizabeth Julianna Footman, November 23, 1785, at Christ Church, Philadelphia. He studied medicine at Edinburgh and afterwards took a course in London and Paris. He removed to Burlington, N. J., in 1795, after having studied under Dr. Bond. In Burlington he became the partner of Dr. McIlvain, his brother-in-law. He was a man of agreeable, hearty manner and fond of horses. He had an excellent practice. A picture of him taken in London shows him as a student, a handsome youth, with powdered hair, lilac colored coat, gold waistcoat.

Also in the fourth generation we find his first cousin, Joseph Galloway Shippen, M. D., who was the son of Col. Joseph Shippen, A. B., and Jane Galloway. He was born in Plumley, Pa., December 25, 1783, and died September 6, 1857. He married Ann Martha Buckley, November 10, 1814, daughter of Daniel and Sarah (Brooke) Buckley. He graduated from the University of Pennsylvania with the degree of M. D. and was a practicing physician.

In the fifth generation is the name of Joseph Shippen, M. D., who was a son of Dr. Joseph Galloway Shippen and Ann Maria Buckley. Also

in this generation was William Shippen, A. B., M. D., who was a son of Thomas Lee Shippen and Elizabeth Carter Farley Bannister and a grandson of Dr. William Shippen, Jr. He was born in Farley, Pa., January 29, 1792, and was married in Petersburg, Va., February 13, 1817, to Mary Louise Shore, daughter of Thomas and Jane Gray (Wall) Shore of Violet Bank, Va. Dr. Shippen was vice president of the Pennsylvania Historical Society, trustee of the College of New Jersey (1841-1867), graduate of the University of Pennsylvania, M. D., 1814. He studied medicine under Dr. Wistar. He was a demonstrator of anatomy in the university. He died in Philadelphia, June 5, 1867.

In the sixth generation are two of the same name. The first, Edward Shippen, A. B., A. M., M. D., United States Army, was a son of William Shippen, M. D., and Mary Louise Shore. He was born in Farley, Pa., June 23, 1827. He was a graduate of the University of Pennsylvania, class of 1846, and received his M. D. with the class of 1857. He married Rebecca Lloyd (Nicholson) Post, the granddaughter of Judge Hooper Nicholson and Rebecca Lloyd, December 3, 1878. Dr. Shippen was a distinguished surgeon during the Civil war and among other services had charge of the Capitol at Washington, D. C., when it was used as a hospital. He had 1,000 wounded men under his care. Later he was with General Griffin as surgeon in chief of the Fifth Army corps, and then as medical director of the Twenty-third Army corps under General Scofield where he remained during the rest of the war. He died April 22, 1895, in Baltimore, Md.

The second name in the sixth generation is that of Edward Shippen, A. B., A. M., M. D. (rear admiral United States Navy). He was a son of Richard Footman Shippen and Ann Elizabeth Farmer. He was a grandson of Dr. Edward Shippen of the fourth generation. He was born at Singletree, Bordentown, N. J., June 18, 1826, and died at Chestnut Hill, Pa., June 16, 1911. He graduated from Princeton in 1845 and the University of Pennsylvania in 1848. He entered the United States Navy from Pennsylvania as assistant surgeon, August 7, 1849, was made surgeon, April 26, 1861, and sent to the coast of China and Africa and South America and on the European station for four years. He was on the *Congress* when she was destroyed by the *Merrimac* at Newport News, Va., March 8, 1862, and was injured by a shell. He was on the ironclad *New Ironsides* in both the attacks on Fort Fisher and the operation of Bermuda Hundred. He made a Russian cruise under Admiral Farragut, 1870-1. He was chief surgeon at the Naval Academy, Annapolis, Md., and medical inspector in 1871; fleet surgeon of the European Squadron, 1871-3; medical director at the Naval Asylum, 1876; president of the Medical Examining Board of Philadelphia, 1880-2, and for nearly seven years in charge of the Naval Hospital at Philadelphia. He was a writer on medical topics. He was retired in 1888 and in 1907 made rear admiral on the retired list. He was a Fellow of the College of Physicians and Surgeons of Philadelphia; president of the Pennsylvania Genealogical Society;

member of the Pennsylvania Historical Society; commander of the Military Order of the Loyal Legion, Deputy Governor of the Society of Colonial Wars of Pennsylvania; one of the vice presidents of the University Club. He married Mary Catherine Paul on January 13, 1853, daughter of Dr. John Rodman Paul and Elizabeth Duffield Neill of Philadelphia. She was born in Philadelphia, July 23, 1829, and died there January 18, 1905.

In the seventh generation we find three names of men who are first cousins, i. e., Lloyd Parker Shippen, M. D., U. S. N., M. R. C., who is the son of Edward Shippen and Rebecca Lloyd Post. He married Florence Hawley Brush. He graduated from the University of Pennsylvania (1907) and is a member of the Pennsylvania Commandery of the Military Order of the Loyal Legion. Charles Carroll Shippen, M. D., A. B., was the son of William Shippen, A. B., A. M., LL. B., and Achsah Ridgley Carroll. He was born in Philadelphia, Pa., October 29, 1856, and died in Baltimore, Md., November, 1905 (unmarried). He graduated from the University of Maryland in 1879. William Shippen, M. D., U. S. A., son of Thomas Lee Shippen and Jane Gray Gilliam, and grandson of Dr. John Gilliam, was born in Arrowfield, Va., May 21, 1861, and died (unmarried) November 17, 1913, at his home in Petersburg, W. Va. He served twenty years in the United States army as a surgeon.

THE SCHICK TEST, ITS CONTROL, AND ACTIVE IMMUNIZATION AGAINST DIPHTHERIA.

BY ARTHUR I. BLAU, M. D.,
New York.

Diagnostician, Department of Health

I shall endeavor to give a brief outline of the salient features of the Schick test and active immunization against diphtheria. The summary presents a working knowledge of the test and immunization, as practised in the Stuyvesant Branch of the Department of Health. Personal observations from the work carried on in the Stuyvesant Branch Clinic are noted in full. This article should be of particular value to the physicians of the Department, who are doing the Schick test for the Department's patients, and, secondarily, to physicians desiring a concise description of the test and immunization.

The Schick test is a practical and reliable test by which the antitoxic immunity of a person against diphtheria can be determined. The immunization is for the purpose of protection against diphtheria. In the progress of modern medicine the Schick test and active immunization against diphtheria occupy a most prominent and important place. In the determination of the antitoxic immunity of a person against diphtheria the Schick

test is as reliable a diagnostic aid as the Widal is in typhoid fever, or as the Wassermann is in lues. When we realize the prevalence of diphtheria among children, and the high degree of mortality we will appreciate the importance of the Schick test and active immunization in the prophylaxis and final eradication of diphtheria. Since the ages of one to five years is the period in which children are most susceptible to diphtheria and the mortality greatest, the necessity of the application of the test and active immunization early in the child's life, before the age of eighteen months, so that the child may be protected against diphtheria in that crucial period, becomes apparent.

THE SCHICK TEST.

Supplies.—The supplies used are those furnished by the Health Department. Either of two outfits may be used for the test, namely, the capillary or the stock solution.

1. The capillary outfit consists of a capillary tube in a thin wooden box. This tube contains the unheated diphtheria toxin. A second capillary tube in a thin wooden box. This tube has a black mark at one end and contains the heated diphtheria toxin, for use in the control test. The toxin in this capillary tube is the same as that in the first tube, but has been heated to 75° C. for five minutes. The heating destroys the diphtheria toxin, which is the active agent in the positive Schick test, but does not effect the protein substance of the diphtheria bacillus, which produces the pseudoreaction. The black mark on the capillary tube is designed for differentiating the heated from the unheated toxin. Two small vials, each containing ten c. c. of normal saline solution, to be used as diluents for the toxin in the capillary tubes, one vial for the Schick test, and the other for the control. Two small rubber bulbs, one for each capillary tube. The contents of both vials, with the toxin introduced, are sufficient for thirty-five tests and if kept on ice are good for use only twenty-four hours.

2. The stock solution outfit: Since the capillary Schick test outfit can only be used for twenty-four hours, a stock solution can be made which is good for a longer period. The supplies and the method of preparation of the toxin solutions are as follows: One vial containing two c. c. of original diphtheria toxin, from which all stock solutions are made. This toxin is not ready for use. To be used it has to be diluted. If kept on ice, this toxin is good for two months. From the original diphtheria toxin, (a), a primary stock solution is made as follows: One c. c. of this toxin is added to six and a half c. c. of normal saline solution and the mixture shaken. This primary stock solution is not ready for use. To be used it has to be further diluted. If kept on ice, this primary stock solution is good for two weeks. One c. c. of the primary stock solution, (b), is added to ninety-nine c. c. of normal saline, or 1 c. c. of the primary stock solution, (b), is added to 9.9 c. c. of normal saline, or .1 of saline solution is withdrawn from the 10 c. c. saline vial, and that amount (.1) is replaced with a similar amount of the primary stock solution, (b), and the mixture is shaken. This latter

solution is the secondary stock solution. It is the final dilution and ready for use in the Schick test.

TECHNIC OF THE TEST.

Directions for the use of the capillary outfit in the Schick test:

1. Break off one end of the capillary tube not having the black mark.
2. Push the broken end of the tube through the neck of the rubber bulb, until it punctures the diaphragm and enters the cavity of the bulb.
3. Break off the other end of the tube.
4. Expel the contents of the capillary tube into one of the vials containing ten c. c. of saline solution by placing the index finger over the opening in the larger end of the bulb.
5. Rinse the capillary tube by drawing up saline solution several times.
6. Cork the saline vial and shake the diluted toxin.
7. Inject 0.2 c. c. of the diluted toxin, representing one fiftieth M. L. D. for the guineapig, intracutaneously on the flexor surface of the left forearm.

The procedure for the use of the capillary outfit in the control test is identical with that employed in the Schick test, but using the capillary tube with the black mark, and making the injection on the flexor surface of the right forearm.

Directions for the use of the secondary stock solution in the Schick test: Inject 0.2 c. c. of the final dilution, i. e., the secondary stock solution, intracutaneously into the flexor surface of the left forearm, the same way as is used with the capillary toxin. Whenever possible the capillary toxin should be used in preference to the stock toxin in making the Schick tests, as the capillary toxin requires no dilution and no preparation, being ready for use as it is. The stock solution should only be used when Schick tests are infrequently made, and the number of cases to be tested but few. In other words when we wish to have a reserve supply of Schick toxin, to be used as occasion arises, the stock solution is preferred. However, for the general practitioner the capillary toxin is recommended for all occasions. For the control test the capillary control outfit is used in either case, whether the Schick test is made with the toxin in the capillary tube or with the toxin from the stock solution.

METHOD OF INJECTION.

This is the same in all tests, in the capillary Schick test, in the capillary control test and in the stock solution Schick test. The procedure should be uniform in all tests, and conducted as follows: Sterilize the skin with cotton soaked with alcohol and then insert the needle into the skin. An efficient guide for the introduction of the needle into the proper layer of the skin is to be able to see the oval opening of the needle through the superficial layers of skin cells. A definite, blanched, circumscribed, wheellike elevation, the size of a dime, with the markings of the openings of the hair follicles distinct, shows that the injection is properly made. An ordinary one c. c. hypodermic syringe, with a fine half inch steel needle can be used for the injections. The site of the injection need not be covered.

THE REACTIONS.

The reactions should be observed at the end of twenty-four and forty-eight hours, basing the final judgment on the last reading. In case of doubt, a reading should also be made at the end of four days.

1. The positive (+) reaction becomes apparent at the end of from one to four days, generally at the end of two days, at a time when the pseudo element of the reaction has disappeared. It consists of a definitely circumscribed area of redness, from one to two and a half cm. in diameter, with a superficial scaling and a beginning brownish pigmentation. A strongly positive reaction will occasionally show vesiculation of the surface layers of the epithelium. The reaction gradually disappears in from one to four weeks, going through various stages of scaling and pigmentation. After about two weeks a distinct brownish area is seen at the site of the injection.

2. The negative (—) reaction. In most cases nothing is seen at the site of the injection. In a small proportion of cases a pseudoreaction is manifest.

3. The pseudoreaction shows an indefinite area of redness of varying size, surrounded by a secondary areola, which shades into the surrounding skin. The pseudoreaction appears earlier than the positive reaction, in from six to eighteen hours, reaches its height in from twenty-four to thirty-six hours, and has disappeared by the end of from two to four days, at a time when the positive reaction becomes apparent, and may leave a poorly defined area of pigmentation, but generally no scaling.

4. The combined reaction is a reaction showing a positive and a pseudoreaction in one. The positive element of the reaction becomes apparent at the end of from two to four days, at a time when the pseudo element of the reaction has disappeared. The appearance of the positive element of the reaction is that described under 1. The appearance of the pseudo element of the reaction is that described under 3, and resembles the reaction at the site of the control test, if there is a reaction at the control, with which it should be compared.

5. The doubtful (+ —) reaction. At times doubt arises as to what the reaction really is. The reaction may not be typically positive, or typically negative, or typically a pseudoreaction. In such cases the leaning should be toward a positive reading.

6. In the control reaction, as a rule, nothing is manifest at the site of the control test. Occasionally the control test shows a pseudoreaction.

INTERPRETATIONS OF THE REACTIONS.

1. A positive reaction. If the person tested is not immune to diphtheria, the toxin in the Schick test will exert its irritant action, and the reaction is positive. A positive reaction shows that the individual has no antitoxin in his blood, showing that he is not immune to diphtheria, and that he needs active immunization against diphtheria to render him immune against the disease.

2. A negative reaction shows that the individual

is immune against diphtheria, and, therefore, needs no active immunization. It also indicates, in children over eighteen months of age, the development of a natural immunity against diphtheria, which apparently is permanent.

3. A pseudoreaction has the same significance as a negative reaction.

4. A combined reaction has the same significance as a positive reaction.

5. A doubtful reaction should be considered as a positive reaction, and, therefore, requires immunization.

The Schick test is positive between the ages of one and four years in about thirty-two per cent. of normal children. It is positive in a slightly larger proportion of measles cases, in twice as many cases of scarlet fever, and in nearly three times as many cases of poliomyelitis. Susceptibility to one of the less contagious diseases, like poliomyelitis, indicates that the child is more likely to be susceptible to other contagious diseases. After the sixth year the proportion of positive reactions rapidly decreases, being positive in from four to ten per cent. only. In adults eighty-five to ninety-five per cent. of the tests are negative.

ACTIVE IMMUNIZATION.

For active immunization against diphtheria a solution of undiluted diphtheria toxin and antitoxin is used. This mixture of toxinantitoxin is slightly toxic and represents about eighty-five per cent. of an L+ dose of toxin to each unit of antitoxin, there being three units of antitoxin in one c. c. of the mixture. The immunity produced is probably permanent. Three injections, of one c. c. each, irrespective of the age of the individual, of the toxinantitoxin mixture are given at seven days' interval, the first being given as soon as a positive reaction is noted. The injections are made subcutaneously in the arm at the insertion of the deltoid muscle, after having painted the skin where the injection is to be made with iodine. The first injection is made in the right arm, the second in the left, and the third in the right.

The development of an active immunity is determined with the Schick test at the end of three months, i. e., all completed injected cases are tested three months after the last injection, to see whether they are then immune against diphtheria. If the test is negative, the person has been made immune against the disease and the case requires no further attention. If the test is positive the person is not yet immune and has to be reinjected and tested again after three months. By reinjecting those who still give a positive Schick test an active immunity can be developed in almost all susceptible persons.

Figures compiled at the Willard Parker Hospital show that from ninety to ninety-nine per cent. of the retests are negative; after one injection, about sixty per cent. are negative; and after two injections eighty per cent. are negative. As the immunity arising from the injection of toxinantitoxin does not develop until the lapse of from two to twelve weeks, active immunization with toxinanti-

toxin cannot be utilized to protect persons from exposure within that period.

Children between three and eighteen months should be actively immunized with toxinantitoxin, irrespective of the Schick test, so that an efficient immunity is produced during the ages of from one to five years, when the susceptibility of children to diphtheria is the greatest. This is necessary because the protection of the infant from the mother is only temporary, and usually lasts only from about six to nine months. All children over eighteen months of age should be tested with the Schick test, and only those giving a positive reaction should be immunized.

PERSONAL OBSERVATION.

I have conducted a practical study of the Schick test and active immunization against diphtheria with toxinantitoxin in my work in the Stuyvesant Clinic of the Department of Health. The obstacles encountered in my studies were numerous. The difficulties experienced were due, primarily, to the lack of enlightenment on the subject on the part of the parents. The general public knows but little about the Schick test, and about the efficiency of active immunization as a preventive against diphtheria. Those of the public who do know something about the subject are indifferent about it and are reluctant to subject their children to what they believe unnecessary inconvenience, especially in the face of perfect health. People are, of necessity, well versed in the indispensability of curative medicine, but are as yet unappreciative of the value of preventive medicine.

Ignorance and indifference were, however, not the only barriers in the successful completion of the studies undertaken. Having with great labor convinced a large number of the parents of the advisability of bringing their children to the clinic for the Schick tests, we were much less successful in having these children brought to the clinic often enough to complete the tests and the injections. In spite of the frequent and persistent home visits by our nurses to urge prompt attendance we were only successful in a very small proportion of the cases.

Sometimes the child would stay away on account of illness, other times attendance at school or other scholastic duties would detain the child; in still other instances, and not so rarely at that, it was fear that kept the children away. A good many of the mothers having consented to one injection would withhold permission for further injections. Then again, a large proportion of our patients moved before the tests and injections were completed, and no trace could be found of their destination.

On account of these unfavorable influences our research studies could not be complete in all the cases. Of a total of 434 cases Schick tested, seventy never returned for a reading. Of 111 positive Schick cases, only nineteen received the full series of three injections, and of these nineteen cases we were able to retest only twelve. Almost half of our positive cases only received one injection as they never returned subsequently.

RECORD OF THE CASES STUDIED.

Total number of cases Schick tested.....	434
Number of cases not returned for reading.....	70
Balance	364
Reactions:	
Negative	227
Positive	111
Combined	3
Doubtful	23
Total	364
Positive Cases:	
Not injected	28
One injection	49
Two injections	15
Three injections	7
Retested cases	12
Total	111
Retested Cases:	
Not returned for reading.....	2

DEDUCTIONS FROM OUR STUDIES.

It is evident from these figures that more than a third of the children under fourteen years of age are susceptible to diphtheria, that is, have no natural immunity against the disease. The greatest susceptibility is found between one and six years. After the age of six years, the degree of susceptibility gradually diminishes, as shown by our negative Schick tests. Of a total of 227 negative Schick tests, 136 were between the ages of six and fourteen years.

Although the immunity produced by active immunization with toxinantitoxin was not quite 100 per cent. in our series, we can safely deduce that with repeated tests and injections, immunity against diphtheria could be produced in 100 per cent. of the cases. Naturally such results require the diligent cooperation of the patients.

Of our ten retested cases, eight were negative, and only two were positive, showing that with only one series of three injections of toxinantitoxin, we were able to produce an immunity against diphtheria in eighty per cent. of the cases. Had our two positive retested cases returned for further injections, there is no doubt in my mind that we could have made them react negatively to the Schick test, giving us an active immunity in one hundred per cent. of the cases.

Whether the immunity is permanent in all cases, we cannot positively state at the present stage of our investigations. Judging from the studies conducted at the Willard Parker Hospital, once an immunity is established it is probably permanent.

Advances in the knowledge of the medical sciences should be applied for the benefit of mankind. What could benefit humanity more than the prevention of disease? That is really what modern medicine is striving for. The motto now is "not to cure, but to prevent."

Considering the extent of the morbidity and mortality of diphtheria, it would be almost criminal not to utilize to the fullest possible degree the means at our disposal to curtail and check the disease. This can and should be done.

To have success crown our endeavors it is necessary to popularize the Schick test and active immunization both among the profession and the lay public. To begin with, doctors have to familiarize themselves with the technic of the test and the injections. Once that is done, they can urge upon their patients the advantages to be derived from the application of the test and active immunization. The Department of Health is conducting clinics in the different sections of the city, where doctors are instructed on the theory and practice of the test and immunization.

It is not sufficient to merely educate the profession on this important subject, the general public also has to be enlightened. This can be accomplished by means of lectures, films, and popular advertisements both in the newspapers and on bill posters. By such systematic and generalized distribution of knowledge and information, our endeavors surely cannot fail.

417 EAST EIGHTY-THIRD STREET.

NEPHRITIS.

By HYMAN I. GOLDSTEIN, M. D.,

Camden, N. J.

(Concluded from page 259)

Headaches occur which are often severe, commonly occipital or on top of head, may be associated with vomiting and twitchings or convulsions, and must be differentiated from brain tumor. Convulsions and coma are frequently late scenes. Forms of insanity may develop, such as uremic psychoses, delirium, melancholia, confusional insanity, and uremic narcolepsy. There may be much difficulty in diagnosing these cases. No albumin and very few casts may be present in many of these uremic states.

The gastrointestinal symptoms are many and varied. Salivation may occur. Long continued hiccough without fever and if not hysterical may often be uremic. Hiccough with fever occurs in pneumonia, typhoid fever, infections below the diaphragm, and abscess of liver. Riesman emphasizes the fact that vomiting without headache may be due to intestinal obstruction. Dysentery is not uncommon.

Eczema, severe and distressing pruritis, purpura, hemorrhagic diathesis are some of the more common cutaneous manifestations.

The uremic eye changes consist of albuminuric retinitis, depreciation of vision, blue blindness, violet blindness. The retinitis may be degenerative (granular kidney) or exudative and inflammatory (parenchymatous nephritis). Recurring subconjunctival hemorrhages may be uremic (nephritis and arteriosclerosis) in origin. Iritis may occur alone, or with albuminuric choroditis. Retinal hemorrhages and white spots (star shaped) are, of course, the most characteristic. The white or yellowish white spots occur near the macula, and often form a striking wide white area about the papilla (nerve head) or snow bank appearance of the retina (de Schweinitz). The retinal vessels are tortuous and beaded in appearance and less translucent and show whitish stripes (degeneration of walls).

DIAGNOSIS OF UREMIA.

The urine itself may fail as a diagnostic sign. Riesman, Christian and others have repeatedly pointed out that uremia cannot be diagnosed by the urine. Christian says no single renal test is pathognomonic of nephritis or uremia. The whole case, the history, the symptoms and repeated uranalysis must all be considered in reaching a diagnosis of real nephritis and the condition of the renal tissue. Tests of renal function may aid in diagnosis, and in the treatment as they measure the extent and severity of the renal lesion.

The functional tests, such as the Rowntree, Geraghty phenolsulphonophthalein test, the blood urea nitrogen estimation and the renal test meals all help to a correct diagnosis of acute and chronic uremia. There is present polyuria, urine is of low specific gravity, traces only of albumin at times, and few casts. Casts are nearly always present. There may be a fixed low level specific gravity or hypostenuria. Indican has been demonstrated in the

blood in uremia by Moraczewski, Herzfeld and G. Dorner.

Finally, the hypertension, which may show a blood pressure as high as 300 mm. of mercury systolic, and other characteristic cardiovascular changes, such as hypertrophy of the left ventricle, sclerosis and hardening of the vessels, with the frequent presence of systolic murmur and an accentuated aortic second sound without true organic valvular disease, and the eye ground examination complete the diagnosis.

The uremic vomiting must be distinguished from other causes of toxic vomiting such as those accompanying migraine and hyperthyroidism, pregnancy, cyclic or paroxysmal vomiting; and from the vomiting due to gastric crisis of *tabes dorsalis* and strangulated hernia, and alcoholism.

Hyperthyroidism, tuberculosis, diabetes, and other diseases, must be ruled out in cases of uremic psychoneurosis. Eclampsia, alcoholism, meningitis, hysteria, and epilepsy must be ruled out in cases of uremic convulsions and nephritic meningism. The very important and almost constant symptom of headache in uremic patients must be differentiated from the headaches occurring in various chronic intoxications, constipation and biliousness, eyestrain, psychoneurosis, sinusitis, meningitis, migraine, gout, lues, syphilitic periostitis, and brain tumor.

Uremic pericarditis occurs as a not uncommon complication in chronic interstitial nephritis. Of course, pericarditis is most commonly due to rheumatism, tonsillitis, and pneumonia, and any of these conditions may coexist in a uremic patient.

E. C. Segun (2) has emphasized occipital headache as a symptom of uremia. Intermittent headaches have also been mentioned as occurring in uremia by Von Leube. Bronchitis and asthmatic attacks often form part of the symptomatology of chronic and acute uremia. While bronchitis is most frequent, pericarditis is the most fatal.

Sudden blindness, amblyopia, with ringing in the ears with dizziness and more or less deafness have occurred in some of my cases early in the attack and have helped ward off more serious complicating symptoms by warning the patient; my resorting to venesection and the prompt use of depletory remedies have saved life at least at the time. The uremic deafness is probably of central origin; as in the sudden blindness, it is of short duration, lasting only a few days.

Curschmann states that in threatened uremia, the Babinski reflex often becomes positive before increased tendon reflexes or mental disturbance occur. Insomnia of several days duration, followed by hemiplegia, monoplegia or aphasia and paraplegia with pains in the calf muscles, have occurred most unexpectedly in some doubtful cases, with only slight symptoms referable to the kidneys and practically negative urine.

CONVULSIONS.

Uremic or renal asthma is a most constant symptom in uremia and Cheyne-Stokes breathing may occur. These attacks are likely to occur at night. The attacks of renal dyspnea are due to acidosis and

may be excited or made worse by the associated cardiac weakness or pulmonary edema. One of my patients nearly died recently from the pulmonary edema. The breathing may be that of air hunger or Kussmaul type. This hyperpnea may be considered as pathognomonic of acidosis. The acidemia breathing is deep, pauseless, not usually increased in rate, though the respirations may vary in depth, like a modified Cheyne-Stokes breathing, the excursions of the abdomen and thorax are nearly the same with succeeding respirations. Drowsiness may accompany this condition. The convulsions themselves, as stated, are the most characteristic symptoms of uremia. They are epileptiform in type, and they may be local or unilateral. Osler says they are supposed to be due to a local or general edema of the brain and are probably allied to the apoplexia serosa of early writers. They may come on suddenly or be preceded by nausea, vomiting, insomnia, vertigo, headache or dropsy. After the toxic rigidity, clonic spasms with fever and cyanosis and arterial spasm may follow at short intervals. The diagnosis cannot be made by the convulsions alone. In epilepsy convulsions are preceded by an aura, and unconsciousness is total and complete; the patient may bite the tongue and urinate; there is a history of previous convulsions occurring in younger patients. Clonic convulsions are present, after the rigidity subsides. The epileptic cry or shriek is characteristic.

Jacksonian epilepsy consists of convulsions which are usually unilateral and due to a focus of irritation on opposite side of brain. The unconsciousness is not total. General paralysis of the insane is manifested by convulsions which have a tendency to repeat themselves one after another. The Wassermann reaction would be positive, the test should be made with the cerebrospinal fluid and the blood. Acute infectious diseases, such as meningitis, scarlet fever, pneumonia, especially in children, may begin with convulsions.

Convulsions may be due to drugs such as strychnine. They are painful and are started by the slightest irritation. They are not accompanied by loss of consciousness. The jaw muscles may also become affected. The muscles of respiration are involved. Death occurs suddenly, due to respiratory spasm. Intervals of complete relaxation occur. Alcohol may cause convulsions very similar to epilepsy. There is a history of ingestion of some drug. Strychnine convulsions begin with gastric disturbance or tetanic contraction of the extremities. Objects appear green and hyperesthesia of retina occurs. The convulsions are violent from the onset. The gastric contents show strychnine; the course is brief.

Tetanus begins with lockjaw. The first convulsive spasm affects the jaw muscles, and consciousness is preserved. The convulsions later spread downward, the arms and hands escaping. Rigidity is persistent except in the chronic form. The course is prolonged for days or weeks. Cultures made from a discoverable wound may show tetanus bacilli.

In hysteria convulsions seldom occur when pa-

tient is alone. Usually the patient cries continually. There is no total loss of consciousness. The patient is erratic and has a dramatic attitude. Opisthotonus is sometimes present; it lasts a long time, a half hour or so. The patient is often emotional, crying or laughing. Stigmata may be present. The pupils are dilated. Spasms of hysterical laughing or crying may precede the convulsions. An aura is present, as in epilepsy. Globus hystericus, clonus hystericus with vertigo and tinnitus aurium and localized areas of tenderness or hysterogenous zones may be present. Reflex convulsions from parasites, eclampsia, myotonia, muscle spasm of a ticlike character, and Adams-Stokes disease are other conditions which must be differentiated.

Uremic unconsciousness coming on suddenly may simulate cerebral tumor, cerebral hemorrhage or a stroke of apoplexy, alcoholism or meningitis. In uremia there is an indicanemia and not in pseudouremia, and there is no nitrogen retention in pseudouremia. In diabetic coma the presence of sugar in the urine with acetone, the history, and the odor of the breath help make the diagnosis.

Opium poisoning must also be ruled out. Here the pupils are contracted and do not respond to light; the patient may answer rationally when aroused. In uremic coma consciousness is entirely abolished and pupils are generally dilated. In cerebral hemorrhage the pupils may be unequal or dilated; stertorous, flapping respiration is present; there is paralysis, and the urine may be negative.

SOME PHYSIOLOGICAL FACTS.

The secretion of urine is probably controlled through chemical stimuli. Certain substances in the blood, when in excess of a certain concentration, are secreted, because in some way they stimulate the activity of the kidney cells. The increased amount of urine that occurs when there is an increased blood flow through the kidneys is due to the greater amount of these chemical stimuli that pass through the kidneys.

Schaefer and Herring (3) have shown that a substance is contained in extracts of the posterior lobe of the pituitary gland which acts as a stimulating hormone to the kidneys, and it may be that this hormone may function normally. Cow (4) has stated that a stimulating diuretic hormone is formed in the mucous membrane of the intestine. When water is taken this hormone is carried into the blood with the absorbed water and is responsible for the resulting diuresis. It is stated that water taken by mouth causes diuresis, when a similar amount injected directly into the blood may have no effect.

The excretion of the kidney varies with the quantity of blood flowing through it. Landergren and Tigerstedt (5) have shown that when the kidney is in strong functional activity, as may be produced by the action of diuretics, it is a vascular organ. They estimate that in a minute's time, under the action of diuretics, an amount of blood flows through the kidney equal to the weight of the organ; this is an amount from four to nineteen times as great as occurs in the average supply of other organs in the systemic circulation. In strong diuresis, both kid-

neys taken into account, five and six tenths per cent. of the total quantity of blood sent out of the left heart may pass through the kidneys in a minute, although the combined weight of the kidneys makes only sixty-six hundredths per cent. of that of the body. Any vascular dilatation of the small renal vessels will tend to increase the blood flow through it, unless there is at the same time such a general fall of blood pressure as is sufficient to lower the pressure in the renal artery and reduce the driving force of the blood.

As to the urinary secretion, the weight of evidence favors the Bowman-Heidenhain theory, namely, that in the glomeruli water and inorganic salts are produced as an act of secretion, while the urea and related bodies are eliminated through the activity of the epithelial cells in the convoluted tubules.

Some diuretics may cause a genuine secretion while others influence the amount of urine through mechanical or physical influences alone. Saline diuretics probably attract water from the tissues into the blood and thus cause a condition of hydremic plethora, and an increased amount of urine is the result. According to Magnus (6), each inorganic salt has a secretion threshold.

TREATMENT AND PROGNOSIS.

Prognosis should be based chiefly on the history of the case, the symptoms and accidents the patient has had, and the results of the functional tests. The phenolsulphonephthalein test, as described by Rowntree and Geraghty, with the use of either the Dunning or modified Hellige colorimeter and an ampoule of the monosodium salt of phthalein (.006 to 1 c. c.) given either intramuscularly or intravenously. The average normal eliminations after intramuscular injections are fifty per cent. the first hour and eighty-five per cent. after two hours. Following intravenous administration, thirty-five to forty-five per cent. in fifteen minutes; fifty to sixty-five per cent. in thirty minutes and sixty-five to eighty per cent. in the first hour. The bladder should be completely emptied and one measured cubic centimetre of the phthalein solution injected into the lumbar muscles or intravenously. If it is injected intramuscularly, collect the urine excreted during an hour and ten minutes, also during a second hour, and estimate the amount of phthalein excreted, by the colorimeter. If given intravenously, collections and estimations may be made at the end of fifteen or thirty minutes, or an hour (7).

Urease may be used for the estimation of urea in the urine and in the blood. This preparation, soy bean, comes in twenty-five mgm. tablets. By the use of these two tests, a fairly accurate prognosis can be given in the majority of the renal cases. Urine analysis alone is not reliable.

TREATMENT OF ACUTE NEPHRITIS.

Acute nephritis is a curable condition in the majority of the cases. Acute or subacute glomerulonephritis occurs in scarlet fever, endocarditis, streptococcal infection, tonsillitis, appendicitis, influenza, exposure to cold, and other affections. Edema of the face, eyelids, fingers and hands are early symptoms, and treatment should be instituted promptly.

There may be trembling of the fingers, muscular twitchings and paralysis of one limb.

In Hughes shifting paralysis a foot, an eye, or a hand may be affected. Moisture is absent in the axillæ in all cases of acute nephritis. The kidneys must be activated because the patient may not void any urine. Water, which is the best diuretic, should be given in quantities of one, two, or three quarts a day, and water may be given by the Murphy drip. Diuretics, such as theocin, caffeine, agurin, and digitalis, should be avoided in acute nephritis. Orange juice or lemonade should be given.

EDEMA.

In Fischer's opinion, diuretics decrease edema, not because the secretory organs of the body have been stimulated to pull water out of the tissues, but because the diuretics act upon all the tissues of the body, and decrease, directly or indirectly, their hydration capacity and cause shrinking. The water is then thrown off by the kidneys, bowel, skin or lungs. Cohnheim's theory as to the edema is that it is due to increased permeability of the capillary vessels, which is caused by malnutrition or poisoning on account of the nephritis.

Widal believes that the kidneys have a deficient capacity to eliminate sodium chloride and the accumulation of salt in the body causes a retention of water, causing anasarca. Fischer's theory that the edema is due to an acidosis has not received confirmation. All of these workers attribute the edema to a retention of salt and water caused by kidneys' inability to eliminate them adequately.

Epstein, of New York, presented a hypothesis for the production of edema in chronic parenchymatous nephritis. He stated that the loss of protein incurred by the blood serum through the continuous albuminuria caused a decrease in osmotic pressure of the blood, which favored absorption or inhibition and retention of fluid by the tissues. Through a change in the protein composition of the blood plasma a condition was produced which was capable of causing the retention of fluid in the tissues. The increase in the lipid content of the blood, the decrease in the globulin content of the blood serum, and the excessive accumulation of lipoids constitute additional factors which contribute to the causation of edema in chronic parenchymatous nephritis, and interfere with the elimination of salt and water by the kidneys.

As stated, it is well to give the patient who is suffering from acute nephritis plenty of water to drink. The bowels and the skin should be activated. Citrate of magnesia is given. The patient is sponged with hot water; a hot pack consisting of a wet hot blanket is given for twenty minutes. Fortify your patient before the sweating by stimulation with aromatic spirits of ammonia. Permit him to sweat for at least twenty minutes, then use dry blankets. A glass or two of cold lemonade or ice water might make him perspire. Potassium citrate may be given as a mild alkaline diuretic. Enemata and a slow drip of sodium bicarbonate may be administered by rectum. Later, after recovery, Basham's mixture or infusion of digitalis U.S.P., freshly prepared, may be prescribed. If

the patient is comatose eight to ten ounces of blood or more may be removed, and water given by stomach tube or sodium bicarbonate solution by rectum or salt solution by hypodermoclysis. Do not give the sodium bicarbonate solution by skin. Soda solution should be given intravenously, by rectum, or by mouth. Nature has a tendency to cure acute nephritis, and we should not be too meddlesome or too active in the treatment. Many patients with acute nephritis following tonsillitis, influenza, scarlet fever, recover nicely without much treatment, other than by the avoidance of exposure, keeping the patient well covered, out of draughts, and the use of the mildest kinds of laxatives.

In the case of scarlet fever prophylaxis is most important. "Make the diagnosis of acute nephritis in scarlatina before you can see it," says Riesman. Watch the urine. If you find some red blood cells and a little increase in the albumin in the urine, tell the family and predict a probable kidney complication.

In bad cases with much dropsy, either one quart skimmed milk or buttermilk can be given a day. As the patient improves cereals and cocoa with sugar and various milk preparations; potatoes and rice may be ordered; no eggs until later. Either powdered digitalis or the fresh infusion may be used as a diuretic. I find the use of a freshly made U.S.P. preparation of the infusion of digitalis, after the real acuteness of the attack subsides, of great help in many of the cases. In very bad cases one may try thirty grams of digitalis leaves in a poultice over the kidneys or a hot flaxseed poultice may be applied.

After recovery the patients all have some secondary anemia. In these cases Basham's mixture may be given. At the expiration of three to five weeks the urine should be free from albumin. Iron is not of as much value in acute nephritis as it is in the chronic forms.

CHRONIC NEPHRITIS.

Since the blood shows a marked decrease in protein and an increase in lipoids and since the lipoid content increase gives evidence of a grave nutritional disturbance and its effect on the pathological condition of kidney tissue itself, Epstein advises to increase the protein content of blood and thus help regain its normal osmotic power and to remove or cause reabsorption by the tissues of the excessive lipoids. He advises, therefore, a removal of quantities of blood from the patient and massive infusions or transfusions of healthy blood in equal quantities. 1. The removal of the patient's blood avoids circulatory embarrassment and removes some excessive lipoids in the cases of chronic parenchymatous nephritis. 2. A proper administration of a high protein and fat poor diet is most important. It should consist of 1280 to 2500 calories daily. Fats should be excluded. Lean veal, lean ham, whites of eggs, oysters, lima beans, lentils, green peas, oatmeal, rice, skimmed milk, cocoa, split peas may be ordered. Large quantities of selected proteins are listed with a minimum of carbohydrates and exclusion of fats. Carbohydrates are restricted in order to allow for a maxi-

imum assimilation of protein and to exclude the greater production and retention of water which is incidental in the metabolism of carbohydrates. The fats are excluded because of the marked increase of faulty substances in the blood. The fluid in edema is made up principally of salts and water. The decrease in protein content of the serum is chiefly due to a loss of protein in the urine. Chaufford, Rechit and Grigaut in 1911 reported an increase in lipid content of the blood in chronic parenchymatous nephritis.

I speak of the diet first in the treatment of chronic nephritis because it is the most important single factor in the handling of these cases. In the usual case of chronic nephritis with edema very slight or absent, and without any of the other more or less acute disturbances, and with the patient feeling fairly well, I allow the following diet:

For breakfast

Grapefruit; cream of wheat and cream; cocoa, toast and butter.

or

Apple sauce; wheatena with cream; zweiback and butter or prunes; farina and cream; sliced oranges; apricots; rolled oats, etc.

For dinner and supper a selection is made from the following list:

Mashed potatoes; rice and cream; cream of onion soup; baked sweet potatoes; pineapple; buttered beets; creamed carrots; brussels sprouts with butter sauce; chocolate cornstarch pudding; stewed corn; chicken fricassee; orange ice; cream of tomato soup; hominy grits; lamb chop and a little sauerkraut for dinner; cream of asparagus soup; berries; small broiled chicken; celery; lettuce; two ounces of roast beef or none at all; baked squash or salmon; spinach; fruit salad; cream of celery soup; broiled trout; all kinds of vegetables; fresh and stewed fruits; fish, perch, cod, haddock, etc. No eggs are allowed. No salt. Meats in great moderation or none at all.

Some physicians advise the use of all kinds of fats, butter, cream and olive oil, in liberal quantities. Some advise the use of carbohydrates and sugar in abundance and eliminate the proteins, while still others, like Epstein, forbid the use of fats and restrict the use of carbohydrates and push the proteins, especially in chronic parenchymatous nephritis. I believe that a conservative happy medium of the three is, after all, the most satisfactory for all concerned.

If the patient becomes dropsical, order him to bed. Protect him with warm flannels. Order a milk diet and fruit juices. Fruit juices are very good in chronic cases of nephritis. Some diuretic should be used with caution; first, it is advisable to start with digitalis. Later, if necessary, three to five decigrams of theobromine may be used with the digitalis.

Agurin, theophorin, theophyllin, theocin, theocin-sodium acetate, diuretin and others may be tried in different cases, as needed, if the ordinary milder diuretics fail. The dropsy often disappears, without the use of any of these active diuretics. The bowels should be opened by elaterium or elaterine and the patient sweated by means of vapor bath, hot bricks and hot blankets, or electric lamps, and if necessary pilocarpine hydrochlorate a few minutes before the hot pack is administered hypodermically. In these cases if there is danger of pul-

monary edema or marked cardiac weakness do not use pilocarpine. A salt free diet helps dispel the dropsy.

Southey tubes are useful for the removal of large quantities of fluid from the legs and thighs; by their use I have removed a half gallon or more fluid in twenty-four hours. Multiple incisions through the skin, in both legs may also be made.

For the nervousness and insomnia I have used sedobrol, as a cup of hot soup or bouillon. Dial (Ciba), barbital or chloral hydrate have given good results. In bad cases if the heart requires stimulation I use digitan and caffen—sodium benzoate, hypodermically. In the uremic cases abstinence from nitrogenous and animal foods is urged. In these cases a lactovegetarian diet is best, with fruit, cereals and oysters allowed on improvement.

In the uremia, convulsions and coma, active treatment of the most vigorous kind is demanded and necessary.

It is most important to bleed the patient; the blood pressure is the guide. The skin and bowels must be kept working. Croton oil, 2 min., in olive oil or butter may be given, as well as elaterium, and later epsom salts with lemonade. Make the patient perspire freely and then stimulate the kidneys if possible.

In some of the cases with simple hypertension, without much demonstrable trouble in the kidneys, the arterial spasm and high blood pressure may be relieved by the use of benzyl benzoate, twenty minims in alcoholic solution every three or four hours. In some of the cases of the type known as climacteric hypertension, I have in a few cases seen surprisingly good results from the use of benzyl benzoate, and corpus luteum or ovarian extract; in others ovarian extract or lutein tablets were used with thyroid extract with favorable results. The iodides and nitrites do not do much good in the cases of essential benign hypertension. Bromides relieve the nervousness, and with tincture of veratrum viride relieve the dizziness and headache.

Anemia is always present; this can be treated by the administration of wine of iron citrate, Basham's mixture, or Bland's mass or by the hypodermic injections of citrate of iron, starting with small doses to avoid vomiting and faintness after its use.

Sometimes the patient's embarrassment of the heart suddenly increases and persists, due to a hydrothorax—this is likely to occur in dropsical cases. Here we must tap the chest, and if necessary the abdominal ascites should also be relieved by tapping. Pulmonary edema and albuminous expectoration after thoracentesis may be prevented by the administration of one sixth grain of morphine sulphate and one one hundred and fiftieth grain of atropine. The aspiration should be performed slowly and thoracentesis should be stopped as soon as the patient begins to cough persistently or becomes markedly dyspneic. Open pleural puncture as described by Schmidt may be tried instead of the usual method of thoracentesis.

ACIDOSIS.

This condition is relieved and reduced by the use of bicarbonate of soda solution. In all forms of acidosis, alkalies are indicated. They may be ad-

ministered by mouth, or intravenously, or by rectum. Avoid the subcutaneous administration of bicarbonate of soda solution. When a solution of bicarbonate of soda solution is boiled carbon dioxide is given off and sodium carbonate is formed. This is irritating. It has therefore been advised to pass a current of carbon dioxide through the solution until it is no longer colored by phenolphthalein. Oscar Schloss has found that bicarbonate of soda in bulk is always sterile. It is probably therefore sufficient to add the bicarbonate, with proper precautions, to sterile water according to Howland and Marriott.

In adults and older children 300 to 400 c. c. of the bicarbonate solution may be injected; in small infants not more than 75 to 100 c. c. Alkalosis must, however, be avoided. Edema may occur, but is usually of no serious consequence. Sometimes in young children tetany may occur following administration of soda solution—where such condition is feared administer a solution of magnesium sulphate subcutaneously—when large doses of the sodium bicarbonate solution are to be given (just as in idiopathic tetany), a four per cent. glucose solution can also be used.

In conclusion every patient with kidney disease must be carefully studied, and treated as an individual. No set rules apply to any one case. It is to be remembered, and it has been emphasized by Christian and others, that in nephritis as such, in uncomplicated nephritis of all types, diuretics are either not indicated because there is no need for increased urinary output, or where there is need for diuresis to remove edema or toxins, they do no good. In other words, in nephritis, as such, diuretics should not be pushed.

Reduction of fluid intake, salt poor diet, sweating, purging, and the use of alkaline remedies, with Southey tubes, or punctures, are far better for removing the edema. For toxic symptoms, bleeding, purging, sweating, and alkaline treatment are more efficacious than diuretic drugs. On the other hand, in patients with cardiac insufficiency and relatively little organic lesion diuretics are extremely useful to aid in the removal of fluid accumulated in the body. They are most efficient when given after a short period of digitalis (digitan, digalen, digipuratum, or powdered digitalis) therapy. In cases of edema of renal origin without cardiac insufficiency, digitalis alone produces no diuresis and when followed by a diuretic drug little or no increased urine flow results.

Theocin, with or without pulv. scillae or fluid extract apocynum cannabinum or cymarum, was in some of my cases more effectual than theobromin sodium salicylate, caffein, and potassium acetate in producing diuresis. However, when edema is in large part due to renal insufficiency, theocin, or agurin, or theophyllin or any other diuretic drug, fails to remove the fluid. They are, however, effectual in increasing urine output in cases associated with cardiac insufficiency.

ARRHYTHMIA.

In some of my nephritic cases, patients who were troubled with arrhythmia, paroxysmal or periodical attacks, and at times anginal spells, I used cactus grandiflorus, fresh tincture and convallaria

majalis, fresh fluid extract with or without tincture of prunus Virginia. Bromides and chloral hydrate in small doses do good, especially in older patients.

What I want to emphasize is the importance of infection in many of our cases of nephritis, especially in children. Such diseases as tonsillitis, appendicitis, sinusitis, and suppurative otitis media; chronic tooth infection and other focal infections; influenza, scarlet fever, and various septic conditions are important factors in the causation of acute and even subacute and chronic nephritis. I have seen a fairly large number of cases of nephritis in children following influenza, tonsillitis, and other acute infections of the nose, throat, ear, and appendicitis and enterocolitis. I could make a formidable list of these cases that would make interesting reading, but this is unnecessary in a paper of this kind, except to call attention to the fact that we must in the future take more interest in the cases of apparent slight acute infections, because of the frequent occurrence of a nephritis which may start as an acute condition, continuing into a chronic nephritis. Many cases of chronic nephritis in children are often of such mild character, and present such a totally different picture from chronic nephritis in the adult, that we often do not see these cases until long after the attack of a mild scarlet fever or a touch of diphtheria, or a quinsy tonsillitis or a touch of grippe or influenza. When these children happen to pick up another mild attack of an acute infection of some sort, there is an exacerbation of the chronic nephritic condition. Then it is that a flood of light strikes us and we discover we were dealing with a case of chronic nephritis in a child.

Most often the blood pressure is not elevated, but I have seen cases in children with blood pressure varying from 140 to 244 systolic and up to 130 and 140 diastolic. The urine often only shows a small quantity of albumin and possibly a few casts of the granular and hyaline varieties. There is an absence of cardiac hypertrophy, although I reported a case some time ago in a girl with an enormous heart complicating a case of nephritis—here the cardiac condition was primary. Of course, as Tyson has stated, prognosis is much more favorable if the heart disease is primary, and the renal disease secondary, even if there is extreme dropsy. Ordinarily cardiac hypertrophy following primary renal disease, is more marked than in primary heart disease. In primary renal disease, even in some of the cases occurring in children, the hypertrophy is principally of the left heart, whereas if heart disease is primary we get enlargement (and dilatation) also to the right.

There are many characteristic findings in adult renal disease which are totally absent in children. I have used in children, especially when acidosis may appear imminent, four per cent. bicarbonate solution by rectum and small doses of bicarbonate of soda and sodium citrate by mouth with splendid results. In these cases (infants and children) water should be given by mouth, by rectum, or intraperitoneally. The injection of water can best be made with a short needle, slowly, with all aseptic precautions, in the median line below the umbilicus;

as much as 300 c. c. may be given to a small infant. The fluid is absorbed gradually without throwing any strain on the circulation.

RÉSUMÉ AND SUMMARY.

1. The importance of focal infection in the production of systemic disease has been emphasized by the work of Frank Billings and others. The relation of foci of infection such as appendicitis, gall-bladder disease (cholecystitis and cholelithiasis), tonsillitis, endocarditis, prostatitis, otitis media and osteomyelitis, to nephritis, especially of the parenchymatous type, must be remembered.

2. The previous history of the patient and especially a history of any recent ailments and infectious disease such as scarlet fever, pneumonia, typhoid fever, influenza, has an important bearing on the diagnosis and prognosis and treatment of the renal condition in each particular case under study. One must not forget, however, that many cases of albuminuria are due to local sources of infection, which clear up entirely after the focus of infection is removed. In these cases medication and dietetics have no important place. The cases show no evidences of disturbed renal function and no definite renal disease is present in these symptomatic albuminurias. Barker and Smith (8), Riesman (9), Thomas, Cabot and others, have called attention to the importance of focal conditions to these so-called innocent and harmless albuminurias.

3. Diagnosis must be made from cyclic and orthostatic albuminuria, another allied condition—the diagnosis and prognosis can be made more accurately by blood chemical test and by renal function tests than by urine analysis. By determining the proportion of the urea in the blood to that excreted in the urine according to Ambard's laws and formula derived therefrom, an idea as to the power of the body to excrete urea can be obtained (10). As the urea in the blood increases it exercises a correspondingly greater diuretic stimulus, and the urinary urea rises proportionately. That is, in any given person Ambard's constant does not change even though the blood urea fluctuates very markedly. Therefore, this gives us a means of determining very accurately the degree of renal function present. Blood urea (the resultant of dietetic regulation and renal function) varies widely. Ambard's constant remains fixed unless the disease process changes and renal function either improves or deteriorates.

4. Dietetic treatment is of the greatest importance in the handling of cases of nephritis. The blood urea and creatinin content gives us indications for dietetic therapy. Ambard's constant furnishes information as to the progress of nephritis and indicates renal function when the blood urea may be as low as the result of dietetic therapy: 0.09 or less equals normal, 0.351 or over is a sign of impending danger (11). McLean's normal figure is 80 or higher and a change for the worse is indicated by a lowering of the constant (12).

5. Drug therapy is only occasionally of considerable help in true chronic nephritis. Diuretics and digitalis do good in cardiac cases where the kidneys fail. Digitalis, theocin, diuretin, caffen sodium

benzoate, potassium citrate, and other drugs may prolong life and stimulate the kidneys to increased action for a brief period only in chronic renal cases with poor kidney function, but sooner or later fail absolutely. Frequently patients with serious primary renal disease fail to respond to any medication—and it is important to keep this in mind, because more harm than good may be done by overmedication and meddling therapy in these cases. The phthalein test is an indication of progress in nephritis, and reveals the course of the disease as affected by therapeutic measures. Its prognostic value as to immediate and ultimate outlook and as to advancement of disease of the kidney as far as its function is concerned, is great, and an aid in the supervision of such cases. Chronic interstitial nephritis is an incurable disease. An active, comfortable life, however, is often compatible with this disease for many years. Chronic parenchymatous nephritis, on the other hand, is a very grave and serious condition which kills in two or three or four years. Change of climate, change of occupation, may help to prolong life. T. C. Janeway (13) says: "Caffen in small doses may give good results in edema cases."

In uremic cases the total amount of fluid administered should be at least 2,500 to 3,000 c. c. in twenty-four hours. You may give a ten per cent. glucose solution by mouth or by the stomach tube if the patient is unconscious. W. W. Palmer (14) has shown that acidosis occurs in many cases of severe nephritis as a result of kidney deficiency—here there is a deficient elimination of acid. Marriott and Howland have suggested the administration of calcium as an aid to the elimination of phosphates which are increased in nephritis. Bicarbonate of soda may be used with caution. The kidney holds back the alkali and therefore alkalosis may result. Note the depth of breathing and carbon dioxide tension in the alveolar air, and the quantity of carbonate in the blood as to the amount of alkali to be administered. Frothingham and Smillie (15) have shown how the nonprotein nitrogen could be diminished in the blood by a low protein diet. Finally, uric acid concentration of the blood is the most delicate test of renal function at our disposal. The first to increase in the blood is uric acid, next urea—while creatinin (16) increases in the blood only after considerable retention of urea had taken place and the nephritis was rather far advanced; that cases with five mg. of creatinin or more almost invariably have a bad prognosis and when the blood nitrogen reaches sixty-five to the 100 c. c. the patient is in serious danger. Five mg. creatinin and sixty to sixty-five mg. urea nitrogen in 100 c. c. blood is a death verdict for the patient—the prognosis being absolutely hopeless in many of these cases.

A. R. ELLIOTT PUBLISHING COMPANY,
Publishers, 66 West Broadway, New York.

Subscription Price: Under Domestic Postage, \$6; Foreign
Postage, \$8; Single copies, fifty cents.

Remittances should be made by New York Exchange, post office
or express money order, payable to A. R. Elliott Publishing Co.,
or by registered mail, as the publishers are not responsible for
money sent by unregistered mail.

Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, SATURDAY, AUGUST 28, 1920.

PHYSICIAN AUTHORS—DR. ARTHUR SCHNITZLER.

As a rule, when physicians become eminently successful in literature and the rewards from the product of their pen mount to flattering heights, they give up the practice of medicine and devote their whole time to writing, feeling, no doubt, that circumstances do not warrant their serving two masters. There are always exceptions to prove every rule, and Dr. Arthur Schnitzler of Vienna is one of these. Despite the position he has won as a playwright and novelist throughout Europe and, in lesser degree, in America, he still clings, at the age of fifty-eight, to his first love, unremittingly attending to his activities as a general practitioner and maintaining his connection with the Clinical Hospital of Vienna, in which city he was born in 1862.

To the bulk of Americans Dr. Arthur Schnitzler is not very well known, but there is every reason to believe that in course of time he will be a familiar literary figure. For Dr. Schnitzler is one of the few great masters in modern literature. It is his frankness in dealing with some aspects of life, perhaps, that has retarded his introduction to the general reading public of America, but this handicap is being steadily overcome and Dr. Schnitzler's audience in this country is rapidly widening. For many years his plays have been produced in foreign language theaters and a start has been made with them on the English speaking stage, the first of such productions being his *Anatol*, in which John

Barrymore played the title rôle. The vogue of the printed play has also helped to introduce Dr. Schnitzler here, and translations of many of his twenty-five plays and playlets are obtainable. His plays are mostly of the one act type, full of shrewd wit and displaying a wonderful grasp of human nature. The critics are agreed that Dr. Schnitzler is the finest psychologist of the theater today, ranking on a par with Hauptman and Wedekind. All his plays, and the novels, too, have their satiric and comic side, even those in which tragedy is the predominant note, and as for those in which comedy is uppermost, there is always a vein of tragedy. There is no man writing today who gives us, in plays, novels and short stories, a more incisive dissection of human yearnings and foibles than Dr. Schnitzler.

The atmosphere of Vienna permeates all Dr. Schnitzler's work, for he has an unbounded love for the once gay old capital of the Austrian empire, and it will be interesting to watch his future treatment of the life of the city now that it has fallen on evil days. When what was formerly Austria-Hungary was fretsawed into an economic picture puzzle, Vienna, with a population of more than two millions, was left suspended, as it were, in midair. Where once it was the twin capital of a vast empire, it is now the centre of a tiny country that is hardly more than a suburb, and the consequences are, to say the least, distressing. But that it will continue to be a source of inspiration to Dr. Schnitzler there is no doubt, for he is still there in the midst of the new life with an observant mind and a rich storehouse of memory.

When Dr. Schnitzler adopted the practice of medicine he followed in the footsteps of his father, Dr. Johann Schnitzler, who was a famous laryngologist. He got his medical degree in 1885 at the University of Vienna and four years later began that connection with the Clinical Hospital which he still maintains. Meanwhile he contributed to *Weinar Klinische Rundschau*, a medical review of which his father was editor and publisher, and also contributed sketches, stories and poems to other publications. His hobby at this period seems to have been the investigation of psychic phenomena, for he published an article of comprehensive scope on the treatment of certain diseases by hypnotism and suggestion. He then went to London and there wrote his *London Letters*, exclusively devoted to medical subjects of wide range and variety. His original writings on medical subjects and occasional excursions into the byways of medicine are exceedingly voluminous.

They culminated in an exhaustive reference work compiled by him and his father, entitled, *Clinical Atlas of Laryngology and Rhinology*.

Although Dr. Schnitzler numerically is fifty-eight years old, he is said to possess an aliveness that would mean youth at any age. He is one of those men who seem to defy old age. An interviewer who chatted with him recently in his beloved Vienna tells us that his gray blue eyes are warm and bright, and that his ample brown hair and trimmed beard give no hint of his years, in spite of the gray in them. He is rather square in build and therefore looks shorter than he is, and his muscles are as hard as iron. He gives the impression of a man who has taken the best bodily care of himself and his appearance gives him dominance in any group. But although Dr. Schnitzler seems to defy time, we know that he has given it considerable profound thought, for his latest work, a novel, *Casanova's Homegoing*, is founded on the horror of growing old. "A merciless soul vivisection" this book has been called, flawless both as a work of art and as a grim human document. The verdict is that of a European critic. We may have to wait a few years before we in America are able to verify it.

PRODIGIOUS MENTAL CALCULATORS.

The first prodigy in mental calculation was Nichomachos, about whom little is known. It has also been stated that the African slave traders were apt mental calculators, but no particular example has been reported in old literature. Mathieu le Coq, who lived in Italy about 1660, appears to have solved the most difficult rules of arithmetic at the age of six years although he did not write or read. If this statement is not completely legendary it places in evidence two characteristics almost constantly found in families of prodigious mental calculators—precocity and ignorance.

Tom Fuller, surnamed the negro calculator, is a curious example of an ignorant mental calculator. He knew neither how to read nor write and died at the age of eighty years without having learned. A contemporary of the negro was Jedediah Buxton, who lived in England from 1702 to 1762. He was a poor laborer who, although the son of a schoolmaster, had never received any instruction and could not even write his name. It is said that he was far below the average intellectually and it was with the greatest difficulty that he could maintain his numerous family. He fished in summer and worked as a thresher in winter. He pushed his mania for calculation to such an extent that when he came to London to be examined by the

Royal Society and was taken to see the play of Richard III he fixed his attention during the dances on the number of steps executed. There were 5,202 of them but he only occupied himself in counting the number of words spoken by the actors, 12,445, and this was found exact. He had learned the multiplication table and this was the only instruction he had ever received. Beside, he preserved in his memory a certain number of products which facilitated his calculation and were, so to speak, landmarks. He always reduced lengths to a peculiar scale, the thickness of a hair, and he well knew how many of these thicknesses there were to a mile. Finally, he had a very remarkable *coup d'oeil* and judgment of space, for he had only to walk over extensive grounds, taking long steps, after which he could give the exact surface. Like Fuller, he died at an advanced age, showing that these prodigies do not die young, as some have maintained.

Mathematicians who have been remarkable calculators represent a type distinct from prodigious calculators. Calculators like Fuller or Buxton remain such all their lives. They have not a mind open to mathematics and profit little, if at all, from any instruction given them. From infancy, mathematicians show a remarkable disposition for mental calculation, but for them this is simply an accident in their existence and they are destined to soar higher. Such is the case of Ampere, who from the age of four carried out long operations of mental calculation with the use of small pebbles, although he did not know the alphabet or figures, De Gausse, regarded as the greatest geometrician of the century, was a prodigious calculator when hardly three years old. In 1810, Zerah Colburn gave exhibitions in the large cities of America and Europe. He was an individual of mean intelligence and yet he maintained that he should be regarded as the greatest mind of the times. He was backward mentally, incapable of any practical application and, like his predecessor, a specialist at figures, but obdurate to all else. His faculties as a calculator developed spontaneously before he could write or read. Mangiamele, a little Sicilian shepherd, was ten years old when he came to Paris to be examined by Arago in 1837. He had discovered procedures of calculation which he used to solve intricate problems. On all other questions his knowledge was more than rudimentary. Dase, born in 1824, was a mental calculator of great note who not only was a prodigy but was also useful to science. To him is principally due the calculation of natural logarithms or numbers from one to a million. Yet he was a calculator in the strict sense

of the word; he would never learn the simplest geometrical proposition and in general had a very obtuse intellect.

Henri Wondeux, a young shepherd of Touraine, who was the object of a report by Cauchy at the Paris Academy of Science, easily carried out mentally the most varied arithmetical operation. He devised procedures, sometimes remarkable, for solving many problems usually treated by algebra. His memory for figures was highly developed and he could remember numbers composed of twenty-four figures. In everything else his memory was faulty. Bidder is a type by himself in the family of calculators. Born in most modest conditions he became through his intelligence one of the most distinguished men of science of his day. At no time in his life did he lose his aptitude for mental calculation, which increased with years, a fact that distinguished him from other calculators. His mental gifts were in part transmitted to his son and grandsons. This is the only case in which hereditary influence has been noted. In 1892, Jacques Inandi was presented at the Paris Academy of Science and Charcot was one of the commission designated to examine him, while more recently another case has been studied in France by Desrullés. The subject, Fleury by name, was born blind, and although not so prodigious as Inandi still he can be placed in the call of subjects under consideration.

The most recent work on the subject is Huntziger's thesis (Paris, 1913). This writer points out that there is a congenital disposition in these subjects, affirmed by the precocity of the phenomenon. Neither heredity nor environment plays any part, at least in most instances. The subject develops only a single memory, that of figures, and this special mnemonic faculty attains extraordinary proportions in some. They all have almost identical procedures for carrying out their mental calculations but they are not those of ordinary arithmeticians, and Huntziger finds that almost all natural calculators remain ignorant during their lives.

SOME CONCLUSIONS AS TO LEPROSY.

While the complacently resigned were pronouncing leprosy incurable, scientists and medical missionaries, great hearted men, have been and are incessantly toiling over its prevention and cure. The findings of the Leper Mission Conference in India last month are:

That leprosy is contagious, but slowly. It is not directly hereditary, children being free at birth, but susceptible at an early age. It is necessary to promote the earliest possible separation of infants from infected leper parents. The Conference believes

leprosy could be stamped out in India if all lepers were segregated, but as this presents many initial difficulties the segregation of pauper lepers should be first undertaken. The present type of mission asylum with sympathetic Christian management affords the best means of effecting a voluntary segregation.

For amending the Indian Lepers Act of 1908 the training of medical assistants in diagnosis and treatment was urged; the equipping of all leper institutions with a suitable laboratory; when the separation of the sexes is impracticable, the couple should be allowed to live together only on the understanding that any children born shall be separated from them as early as possible also that one parent, if presenting good prospects of recovery, should be separated from the leprous one. It was added that the method of treatment with the salts of fatty acid introduced by Sir Leonard Rogers had been lately tested by fourteen medical officers and assistants on lepers throughout India with most favorable results, seventy-two advanced cases showing marked improvement, but much research into this is still needed. The amendments are approved by foremost men such as Sir Ronald Ross. Sir Leslie Rogers, of the School of Tropical Medicine, referred recently to the shabby treatment the Medical Service in India had received from the bureaucratic Government in regard to special research, saying his own expenses were far in excess of his income. The appeal comes from men fighting daily, the ignorance of it from men who have only met lepers in the pages of Blue Books and—to them—tiresomely long reports.

News Items.

Honor for Dr. Biggs.—Dr. Hermann M. Biggs, health commissioner of New York State, has been awarded the honorary degree of Doctor of Science by Harvard University.

Huebner Prize Awarded.—The Huebner Prize for the best work on pediatrics has been awarded to Dr. Arvo Ylppö of Helsingfors, assistant at the Kaiserin-Augusta-Viktoria Haus at Charlottenburg, Germany.

Georgia Medical Association Officers.—At its annual meeting held in Macon in May, the Medical Association of Georgia elected the following officers: president, Dr. Edward T. Coleman, of Graymont; vice-presidents, Dr. Theodore E. Oertel, of Augusta, and Dr. Fred L. Webb, of Macon; secretary-treasurer, Dr. Allen H. Bunce, of Atlanta.

Changes in Mercy Hospital Staff.—The following appointments have been made to the staff of Mercy Hospital, Baltimore: Superintendent, Dr. Irwin O. Ridgely; Dr. L. H. Brumback, Dr. Hazen G. Chamberlain, Dr. J. A. Clarkens; Dr. John J. Erwin, Dr. Andrew J. Gillis, Dr. Benjamin Gold, Dr. W. F. Martin, Dr. E. L. Kaufman, Dr. W. K. McGill, Dr. J. W. Martindale, Dr. William J. B. Orr, Dr. Daniel J. Pessagno, Dr. J. M. Robinson, Dr. Sanford M. Rosenthal, Dr. Vernon I. Smith, and Dr. Robert B. White.

United States Civil Service.—The United States Civil Service Commission announces examinations for district medical officer (\$1,800-\$3,000) and assistant medical officer (\$1,800-\$2,750) in the rehabilitation division of the Federal Board for Vocational Education.

John B. Murphy Memorial.—It is proposed to erect a memorial to the late Dr. John B. Murphy, of Chicago, in the form of the John B. Murphy Memorial Hall of the American College of Surgeons, on a site in Chicago and at an estimated cost of \$500,000. The building would furnish a meeting place for medical societies, and it is also proposed to maintain there a pantheon of American medicine and surgery. The John B. Murphy Memorial Association is undertaking to raise subscriptions for the amount. One hundred thousand dollars has already been pledged provided the balance of the requisite sum is obtained.

Gift from English to American Surgeons.—Word comes from London that a silver gilt mace is to be presented by British surgeons to the American College of Surgeons (which includes Canada) as a memento of the work done in cooperation by British and American surgeons during the war. The gift is the suggestion of Sir Berkeley Moynihan, who has worked in collaboration with Sir Anthony Bowlby and Sir D'Arcy Power. The mace is the work of Mr. Omar Ramsden, who has modeled the head of the mace on the lines of a surgeon's mortar dug up in a Salonika trench. The design includes maple leaves and American eagles, the badges of the British and American Army Medical Corps, and the serpents of Æsculapius, while the name is introduced of Philip Syng Physick (1768-1837), the father of American surgery, who was a pupil of John Hunter and an ex-house surgeon at St. George's Hospital. An inscription reads: "From the consulting surgeons of the British Armies to the American College of Surgeons in memory of mutual work and good fellowship in the Great War."

New York State Vital Statistics.—The May death rate in New York state was 12.7, which is the lowest May death rate on record for the state as a whole and is 2.3 points lower than the May average in the five years 1913-17. The infant mortality, 88 deaths under one year in 1,000 live births, is 9 points below the May average in the five year period mentioned.

The communicable diseases which showed a case incidence in the state as a whole of 100 or more in 100,000 population were measles 1,175.1, syphilis 315.4, tuberculosis (all forms) 247.1, diphtheria 221.5, pneumonia (all forms) 198.6, whooping cough 172.9, scarlet fever 156.1, mumps 140.3, and chickenpox 133.8. The communicable diseases which showed a death rate of 10 or more in 100,000 population were tuberculosis (all forms) 127.8, pneumonia (all forms) 125.9, measles 14.5, diphtheria 14.5, and epidemic influenza 13.1.

Syphilis continues to show the notably high case rate which prevailed during the first quarter of 1920. The May rate of 312.6 represents the discovery during that month of 2,930 cases of the disease.

Dr. Gorgas Buried in Arlington.—The body of Major General William C. Gorgas was buried August 16th at Arlington National Cemetery. Preceding the army ritual at the grave, services were held at the Church of the Epiphany, attended by Cabinet members, members of the diplomatic corps, and representatives of American and foreign scientific societies. Among the pallbearers were Col. Sir William Smith, of the Royal Institute of Public Hygiene; Major General Merritte W. Ireland; Rear Admirals W. C. Braisted and Cary T. Grayson, and former Surgeon General Rupert Blue of the Public Health Service.

Rural Consultation Clinic.—The New York State Department of Health recently held at Goshen the first rural consultation clinic in the country, to assist local physicians in difficult diagnoses. It is planned to establish visiting clinics in other localities which are without x ray machines and needed laboratory apparatus. In conducting the clinic the following subdivisions were used: diseases of children, diseases of adult life, diseases of women, mental and nervous disorders; orthopedic surgery, venereal diseases, and oral surgery. Among the physicians who were to take part in the clinic are: Dr. T. Ordway, dean and professor of medicine, Albany Medical College; Dr. H. L. K. Shaw, president-elect, American Child Hygiene Association, and professor of diseases of children, Albany Medical College; Dr. J. F. Nagle, attending physician, Bellevue Hospital; Dr. E. J. Wynkoop, professor of diseases of children, Syracuse Medical College; Dr. G. W. Partridge, Bellevue and Post Graduate Hospitals, New York City; Dr. C. D. Post, professor of medicine, Syracuse Medical College; Dr. Charles M. Dunne, Norwich, N. Y.; Dr. F. W. Barrows, state medical instructor of schools; Dr. L. W. Hubbard, Dr. M. F. Lent and Dr. W. E. Youland, State Health Department; Dr. A. S. Moore, Dr. W. E. Kelly and Dr. W. A. Schmitz, Middletown State Hospital; Dr. W. O. Sandy and Dr. E. W. Fuller, State Commission for Feeble Minded, and Dr. C. B. Witter.

Died.

BELL.—In Williamsport, Pa., on Monday, August 9th, Dr. G. FRANKLIN BELL, aged fifty-nine years.

COOPER.—In New York, N. Y., on Monday, August 9th, Dr. Sherman Cooper, aged eighty-eight years.

DAVIS.—In Mackinac, Mich., Dr. Olga Davis, of Chicago, aged forty-five years.

HEIST.—In Philadelphia, Pa., on Sunday, August 8th, Dr. George David Heist, aged thirty-five years.

HEUEL.—In New York, N. Y., on Wednesday, August 11th, Dr. Emil Heuel, aged fifty-five years.

HOEY.—In San Francisco, Cal., on Sunday, August 1st, Dr. Matthew J. Hoey, aged thirty-eight years.

KARLSLOE.—In New York, N. Y., on Sunday, August 8th, Dr. William J. Karlsloe, aged seventy-one years.

MERENESS.—In Albany, N. Y., on Wednesday, August 4th, Dr. Henry E. Mereness, aged seventy-one years.

SHERMAN.—In Rochester, N. Y., on Wednesday, August 4th, Dr. James F. Sherman, aged fifty-eight years.

TILLAPPAUGH.—In Wolcott, N. Y., on Friday, August 6th, Dr. James J. Tillapaugh, aged sixty-three years.

Book Reviews

PSYCHOANALYSIS.

A General Introduction to Psychoanalysis. By Prof. SIGMUND FREUD, LL. D. Authorized Translation. With a Preface by G. STANLEY HALL. New York: Boni & Liveright, 1920. Pp. i-402.

A book of this sort is a rare acquisition. Whether its readers are psychoanalysts or not does not alter the unique value of the work. Naturally their interest will depend upon their point of view, but the inherent worth of the book lies outside this consideration. Perhaps never before has a man of high authority in his field so taken the public into his confidence, so patiently invited them into the scientific details and the broader implications of his subject. Freud's authority has been won through an unremitting toil by which alone he has mastered the field which today may truthfully be acknowledged his. One may not agree with his conclusions, one may dispute the wisdom of choosing such a field as his upon which to expend a life's labor, yet one cannot read this book with an open mind and not perceive that in so far as this has been his realm he has become master within it. Here he spares no pains to share generously the results of his experience with other thinking men and women.

One might even go so far as to admit that it is an actual field of service and because of his faithfulness and skill he has performed a unique work in the history of mankind. He himself makes no boastful suggestion. He is content with lesser claims, his contentment that of the worker too absorbed in his task to dream vain dreams. He merely points out the steps he has taken and calls attention to the lanes and bypaths of future possibilities both in psychotherapy and other psychological fields which temptingly open out of the narrower way already trod. At any rate the content of this book is worthy of close reading in order first to know psychoanalysis in the author himself and then in order to determine on what its assertions to practical success are founded. Psychoanalysis is obtaining ever wider recognition from all circles of interest. The least that one can do in an endeavor to keep abreast of progress is to understand the simple rudiments of a system which is taking such a prominent place.

Of course the book has an especial value to those closely concerned in the study and treatment of psychic disorders, and for that matter for any physician who is continually being brought face to face with all sorts of mental difficulties in his general professional contact with the sick. Here again it is of greatest advantage to approach this method of study of mental disorders through the direct teaching of the leader in psychoanalysis. For the acknowledged psychoanalyst this presentation of the subject is a detailed study of still greater value. It affords a summary of the essential principles of psychoanalysis. It reviews the various elements in the approach to the unconscious mental life and its mechanisms in unified and consecutive order. Any worker in this field admits at once the advantage of frequent review of these fundamental facts and

repeated discussion of their mutual relations. It is both stimulating and instructive to enter again in this simple manner into the author's own practical approach to the unconscious.

The often repeated objections of arbitrariness, narrow resistance to opponents, the insisting upon unfounded speculations, with which Freud's work has long been met, grow feeble before the patient explanations with which Freud has expounded the principles upon which he works and his experience in developing and applying them. His courtesy is manifest toward those who oppose and, more difficult still, toward those who, going part way, have then taken certain hard won hypotheses and twisted them to new meanings, which in some instances at least lack the directness and simplicity of Freud's own thought and practice. His openmindedness toward the real contributions of others as well as toward the possibilities of which he counts his life work only the beginning also win the respect of the reader and incite him to a more than passing interest in the subject presented. Freud has proceeded with such careful steps and his manner of presentation is so scientifically sincere that criticism is disarmed.

It is not possible to do justice to the various positive elements of the book and this for two reasons. Anything more than a brief survey of the topics discussed would only crudely represent what the author has accomplished in so more complete a form. The value of the book can only be reached by a close perusal of its pages. In the second place the book, aside from this instructive sequence of presentation, contains many rich nuggets of psychological truth, especially such as pertain directly to the subjects peculiar to psychoanalysis. The main subjects might be hastily enumerated in the order in which Freud presents them, the psychology of errors as his introduction to the unconscious, then the study of dream content and dream mechanisms, passing from this on to the relations of psychoanalysis and psychiatry with the definite application of the former to interpretation and treatment of the forms of neurotic illness. He touches briefly upon the relation of psychoanalysis to the actual psychotic manifestations but considers this field one of those in which advance is still mostly a matter of future rather than of present accomplishment. Certainly no one can leave the reading of the work without a far profounder knowledge of the psychic life, an understanding enriched both by this wide and profound survey of mental life and its mechanisms and by these many words of revelation with which Freud's interpretation abounds.

Was there not an ancient objection to psychoanalysis and to Freud based on resistance to the sexual content of his work? Any one with such a repugnance would find this a wholesome study. Let him not be deceived, sex is mentioned and in frank detail. It is handled, however, with all the dignified unreserve of a conscientious handling of facts. Again the reader has a straightforward opportunity to question himself whether the assertions

of psychoanalysis are wildly made. If he discovers they are not he finds himself at the end of his reading in possession of a clearer knowledge of the entire sex life of man and of its importance in mental disturbances. He gains an appreciation of its developmental history in each individual. He is able to review thus closely in its various forms the appearances of sex throughout childhood and adult life. He gains also a clearer appreciation of its part in sublimation as well as in partial sublimations and compromise reactions and in determining perversities. He comes to understand the necessity of a balance between the ego and the sex libido and the difficulties which present themselves in making such a balance. Whatever one's medical or psychological faith, one's knowledge of human psychic life is greatly increased by a careful study of this work. At the same time it has its special function as the most complete and comprehensive book on psychoanalysis yet produced.

A CHILD'S MIND.

The World at Seven. By BURNETT STEELE IVEY. Boston: The Stratford Company, 1920.

This little book of verse is interesting, as are all the productions of children. The world of this child was a real world, a very real world inhabited by policemen, grocerymen, candymen, and soldiers. Unlike the poetical works of many children the production of phantasy is not evident. One might recite the poems which are called historical, the ones about Jack the Giant Killer, Cinderella and King Alfred, but in all of these he is only giving back the things he has read about. He does not aspire to create new worlds. He is content to live in the worlds in which he finds himself, or at least to accept another world which has been created for him by someone else. He made his adjustments with ease. Either he has had his own way about things or he encountered few difficulties. A safe prophecy would be that he will find little difficulty in his studies, but unless a radical revolution takes place he will never be an artist. He may become a poet, but he will travel the ways of mediocrity.

A PRIZE NOVEL.

Atlantide (L'Atlantide). By PIERRE BENOIT. Translated by MARY S. TAMPE and MARY ROSS. New York: Duffield & Co.

In France Benoit was awarded a prize of 5,000 francs for having written this highly graphic adventure story. On the whole it recalls H. Rider Haggard. Benoit, no doubt, has done archeological work in the region and used the material he found in making his story. His portrayal of the desert leaves a distinct feeling of its solitude and mystery. The country he has selected is well adapted for the tale which he has told. So convincingly has he written that one stops to wonder about the significance of the rites which are described. Then there is the strange woman, powerful and beautiful, luring men to destruction. Of two comrades, one holds out and the other succumbs to her lures. The passion of the weaker man is so great that he slays his comrade in order to gain the woman, knowing full well that when she tires of him he will be put in a neatly numbered coffin to be placed in a great hall

where she keeps the souvenirs of her conquests. In order to prolong the story or to show more completely the weakness of man, he is allowed to escape. After this stormy adventure he is not contented and is ever seeking to find his way back to the arms of the woman and the niche which has been reserved for him. Such efforts must be rewarded in story books, and the reader is content to know that finally the fatal woman has learned his whereabouts and sent her henchman, the unpronounceable Cegheir-ben-Cheikh after him; if it is what he really wants, after knowing all about it, let him have it by all means.

VENGEANCE WITHOUT INDIANS

Indian Vengeance. By LIVINGSTON FRENCH JONES. Boston: The Stratford Company, 1920.

In this little book one would expect to find material of value to the anthropologist or at least interesting data in regard to Indian customs. From this viewpoint it is disappointing. Instead, we find an ordinary story that might have been told about any group of people in any locality by changing the scenery. The telling of a tale that has little value to science might be forgiven, but when we find the author stating it badly and approaching simple problems in a school boy manner it is more difficult to overlook the transgression.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

PROCEEDINGS OF THE NEW YORK PATHOLOGICAL SOCIETY. New Series, Volume xix, 1919. Illustrated. New York, 1919. Pp. xc-173.

BIENNIAL REPORT OF THE BOARD OF HEALTH FOR THE PARISH OF ORLEANS AND THE CITY OF NEW ORLEANS, 1918-1919. Illustrated. New Orleans: Brandao Printing Co. Pp. vii-133.

FORESTS, WOODS AND TREES IN RELATION TO HYGIENE. By AUGUSTINE HENRY, M. A., F. L. S., M. R. I. A.; Professor of Forestry, Royal College of Science, Dublin. Illustrated. New York: E. P. Dutton & Company. Pp. xii-314.

THE LIFE OF BENJAMIN DISRAELI, EARL OF BEACONSFIELD. By GEO. EARL BUCKLE. In Succession to W. F. MONEY-PENNY. Volume 5 and 6. 1868-1876. With Portraits and Illustrations. New York: The Macmillan Co., 1920. Pp. xii-558.

THE SOUL OF RATIONAL PSYCHOLOGY. By EMANUEL SWEDENBORG. Translated and Edited by FRANK SEWALL, A.M. From the Latin Edition of Dr. J. F. Immanuel Tafel, Tubingen, 1849. Third and Revised Edition. New York: The New-Church Press. Pp. xxxiii-388.

HEALTHY LIVING. By CHARLES-EDWARD AMORY WINSLOW, D.P.H.; Professor of Public Health, Yale Medical School, and Curator of Public Health, American Museum of Natural History. Enlarged Edition. Illustrated. In two volumes. New York and Chicago: Charles E. Merrill Co. Pp. iii-405.

THE MECHANISM AND GRAPHIC REGISTRATION OF THE HEART BEAT. By THOMAS LEWIS, M. D., F. R. S., F. R. C. P., D. Sc.; Honorary Consulting Physician, Ministry of Pensions; Late Consulting Physician in Diseases of the Heart (Eastern Command); Physician of the Staff of the Royal Medical Research Committee, etc. Illustrated. New York: Paul B. Hoeber, 1920. Pp. xx-452.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

TREATMENT OF SURGICAL SHOCK.

BY VINCENT ANTHONY LAPENTA, A. M., M. D.,
Indianapolis, Ind.

The structure of the question as framed naturally excludes any consideration of the several theories advanced for the explanation of this striking phenomenon. Much progress has been made in the elucidation of this question and while limiting this contribution to treatment, some brief reference will occasionally be made to some physiological and physicochemical facts on which my treatment of shock is based.

Answering the question, "How do you treat shock?" it seems that the personal method and ideas of the contributor are what is sought. Adhering to this, no academic reference will be made to the many therapeutic opinions in vogue, but these remarks will be strictly limited to my personal experience and practice.

It does not seem out of place in the consideration of the treatment of surgical shock, to say a few words about its prevention. The occurrence of surgical shock can be largely prevented in the majority of operations of election and in many instances greatly minimized. Traumatic shock resulting from severe injuries is usually treated in the same manner as surgical shock following operations. In the general scheme of prevention, particular attention is paid to the type of patient that is to undergo a major operation. Patients exhibiting neuropathic tendencies, especially when afflicted with diseases associated with disturbances of the central or sympathetic nervous system, such as exophthalmic goitre, are prepared for operation by a preliminary rest cure. Great attention is paid at this time to all the metabolic functions and any disorders, especially acidosis, are corrected before operation. The good to be derived from mental suggestion is never to be overlooked and a great deal can be done by allaying the fear that some patients feel to an exaggerated degree.

The choice of the anesthetic is of great importance. For the sake of brevity, I would say that the anesthesia necessary in a given case is in direct ratio to the severity of the operation and the physical and neurological condition of the patient.

The anesthesia must be sufficient to block as much as possible the conduction of pain stimuli to the vasomotor centre. A preanesthetic injection of morphine is essential and beneficial. In painful operations, especially on sensitive subjects, I believe that the addition of one one hundredth grain of scopolamine is of distinctive value. I have no hesitancy in affirming that it positively diminishes the likelihood of true shock. Among the factors tending to the prevention of shock the importance of gentle manipulations must not be overlooked. In operations on the abdominal viscera, especially when complicated by extensive and firm adhesions, proper protection of the exposed peritoneal surfaces by

warm, moist, gauze pads, sharp dissection of the adhesions and gentle handling of the viscera will greatly aid in minimizing shock. Rough handling of the viscera, severe pulling on mesenteries, forceful tearing of adhesions and undue prolongation of the operation are potent agencies for the production of deep and severe shock. The duration of an operation is intimately connected with the production of shock. I consider it one of the most important elements. A rapidly performed operation is less likely to result in shock even in the absence of precautionary measures than a long slow one, even when performed under ideal conditions. A moderate degree of speed is an essential virtue of a true surgeon.

TREATMENT OF SHOCK.

The treatment must necessarily be adjusted to the degree of shock present and to any complicating factors requiring attention. It is necessary therefore to individualize and it is thus that the best results are obtained. Patients exhibiting a mild degree of shock evidenced by a rapid, but not weak pulse, with increased respiratory movements, will usually respond to applications of external heat to the entire surface of the body. Morphine at proper intervals should be administered. An agent capable of increasing the contractions of the right ventricle, thereby overcoming and preventing venous stasis, is of distinctive value. I believe that pituitrin is the best agent, and I use it in doses of one c. c. every three or four hours in conjunction with morphine, until the pulse shows increased pressure and reduced number of pulsations. Digipuratum and other potent digitalis principles are often of great value. Where it is desired to administer a larger amount of fluid, physiological saline solution is administered by hypodermoclysis. With increasing experience I have come to regard the saline proctoclysis as quite unreliable and, I might add of very uncertain value. If a patient's condition demands the administration of even small amounts of saline solution, it is obvious that this can effectually be accomplished by the hypodermoclysis, avoiding thereby, the uncertainty of results from the rectal route which often amounts to nothing more than a lavage of the anus.

In patients exhibiting severe shock and particularly where there has been considerable loss of blood, intravenous administration of physiologic saline solution is of paramount importance. However, the following precautions must be observed. The amount must not be too large. Seldom should it exceed 750 c. c. It should always be administered slowly, as too rapid administration may cause a rapid dilatation of the right ventricle. The temperature of the solution, at the point of entrance into the vein, must never be below 98.6° F. It is exceedingly easy to add to the shock of the patient by injudicious intravenous medication. Intravenous shock is not a myth and can be induced very read-

ily by rapid administration of the fluid of low temperature, or of imperfect isotonicity. Through several years of observation, I have become convinced that in cases of shock requiring intravenous medication a physiological fluid of colloidal nature approaching that of human plasma would be of great value, and far superior to the ordinary saline solution. The formula I prefer is as follows:

Gelatine,	grams	5
Purified acacia,	grams	2
Sodium chloride,	grams	8.5
Potassium chloride,	grams	2.5
Calcium chloride,	grams	3
Distilled water,		1000

Dissolve the acacia and gelatine in the water at 80° C., filter through hard paper, add salts and re-filter, sterilize in autoclave. When hermetically sealed this solution will keep for some time. In hospital practice it is best to prepare it fresh weekly, in expectation of it being needed.

In patients exhibiting a tendency to acidosis, four gms. of glucose and eight gms. of sodium bicarbonate are added to the solution before filtering. Extreme cases of shock which have been preceded by severe hemorrhage may demand blood transfusion, which we practice, using the citrate method. With judicious use of this solution, transfusion will seldom be found necessary.

In summing up, I wish to state that the bodily temperature must be protected by external heat; that in extreme cases bandaging of the extremities is useful; that morphine must be used fearlessly; that the respiratory centre can be sustained by small doses of strychnine and atropine when indicated, that acidosis must be prevented by timely alkalization; that intravenous medication, while highly beneficial must be judiciously employed; and that last but not least, a hopeful, cheerful demeanor is essential in the presence of the patient and that it is conducive to rapid reestablishment of the vasomotor sensory equilibrium. A nervous, anxious, fretful conduct on the part of the surgeon and attendants cannot fail to react on the patient and create the impression of imminent danger resulting in further exhaustion of sympathetic inhibition with its attendant vasomotor failure.

347 NEWTON CLAYPOOL BLDG.

Milk Injections in the Treatment of Hypertrophied Mammary Glands.—Patel (*Lyon médicale*, April 25, 1920) reports the case of a young woman of twenty-four years with enormous enlargement of the breasts, of sixteen months' standing. The patient was married but had had no child nor miscarriage nor any signs of beginning pregnancy. The breasts enlarged after an attack of influenza in October, 1918, and were estimated to weigh five kilograms each. Aspiration with Bier cups and deep cauterizations were without result, and when first seen by the author the patient was seeking radical treatment. On the advice of Mouriquand Patel administered ten subcutaneous injections of five mils each of human milk on alternate days. On the fifteenth day the breasts began to recede, and thereafter rapidly decreased in size until they resembled deflated balloons.

Treatment of Tuberculous Joints.—Gustav Schwyzer (*Surgery, Gynecology and Obstetrics*, June, 1920) give the following procedure for the treatment of tuberculous joints: As to the methods of operating, incision and so on, we can briefly say that we generally followed Kocher's ways. We always were impressed that through his incisions good access could be gained to the entire diseased area, and it is most important that all the tuberculous tissue be carefully excised by exact dissection. If the disease is confined purely to the synovial membrane of the joint we limit our work entirely to the removal of this membrane, thus avoiding complete ankylosis. But if the bone is involved, the bone ends are exposed by energetic dislocation. We strip back the healthy, outer integuments and turn them back like the cuff of a sleeve. Now the diseased part of the bone is cleanly removed. If we aim at a complete ankylosis, a good apposition of the bones is imperative.

In every case we have used iodoform powder. Contrary to the general routine, we prepared the iodoform powder previously by boiling the same for half an hour in a 1:500 bichloride solution. This powder is rubbed into the entire wound surface, the bone, and the soft tissues. The superfluous, loose part of it is washed away with saline solution. Thus we always have avoided dangerous degrees of iodoform intoxication. In all our resections we drained the wound cavities with rubber tube surrounded by washed out iodoform gauze strips. Our buried suture material consisted of silk and linen. Silkworm gut is the best material for the surface. An abundant amount of absorbent gauze and cotton is used for dressing. A plaster of paris cast is put on before the Esmarch bandage is released. The drains are removed through windows in the cast within a week.

Though the bleeding into the cast was often considerable, we never noticed any alarming hemorrhage. The first cast was always made quite heavy with the intention to leave it on from four to six weeks. After that time the wounds were closed and in affections of the lower extremity the patient was allowed to leave the bed in a lighter cast. None of our patients with hip or knee resections remained in bed longer than six weeks. The patient was sent home in the second cast with the advice to return in two or three months. A much shorter time is needed following operation on the upper extremities. Fortunately in all our cases we did not have to resort to amputation. Only one patient left with a fistula after a resection of the elbowjoint. A second resection eleven months later brought on a definite cure also in this case.

Treatment of Vincent's Angina and Other Similar Infections with Chromic Acid.—W. Dubreuilh (*Journal de médecine de Bordeaux*, March 25, 1920) found the local use of arsenobenzol in Vincent's angina painful and not particularly effective. Methylene blue proved less painful but acted relatively slowly. Chromic acid solution proved more satisfactory than either of these agents. The saturated solution of this acid, such as is produced spontaneously when a bottle of the acid is left unstoppered for a few days, is employed, or, a few drops of water may be placed in a bottle of the

acid so that a few crystals of the acid remain at the bottom. The solution is applied with cotton tightly wound around a small stick of wood; a metallic applicator or glass rod will not do, as the cotton soon loosens and drops off. The cotton should be merely moistened and not thoroughly wet with the solution. The ulcers are immediately rubbed rather firmly with the cotton, so as to detach the false membranes and bring the drug in direct contact with the ulcerated surface. The patient is then at once requested to gargle with water, being cautioned not to swallow any saliva before doing so. The resulting pain is moderate. The patient should thereafter gargle several times a day with hydrogen dioxide solution diluted one in ten or with a one per cent. solution of resorcinol. Next day the ulcer is usually found clean, odorless, and without false membrane. By the third day it is red and undergoing repair. In occasional instances a second application on the fourth or fifth day is required. This treatment may be employed in all lesions similarly produced. In severe mercurial stomatitis it is a useful adjuvant. It does not act on the attending diffuse stomatitis but merely on the ulcers, which are perhaps due to added infection. In the rather frequent form of gingivitis manifested in a linear ulceration about the necks of the teeth, especially of the lower jaw, forming a grayish, gangrenous, and rather painful linear depression, cauterization with concentrated chromic acid cures the condition in a few days. This disorder occurs rather frequently during mercurial treatment, but may also develop independently. In applying the acid in these cases a pointed matchstick, or better a fine Japanese toothpick with a minute amount of cotton wound about it should be used.

Treatment of Lethargic Encephalitis.—A. Netter (*Bulletin de l'Académie de médecine*, March 30, 1920) estimates at 1,500 the number of recent cases of this disorder in the city of Paris, and at 10,000 in the whole of France. Italy and Austria are known likewise to have suffered heavily from it. The author reports the results from various forms of treatment in seventy-two cases. Considering the disease, like epidemic poliomyelitis, to be due to a filterable virus present both in the nervous tissues and in the nose, throat and mouth, he thinks the treatment should be conducted along three particular lines, viz., neutralization of the virus directly in the nerve centres by the use of a specific or nonspecific bactericidal preparation; elimination of the poison by various routes, and stimulation of the general defensive activity of the organism. The first of these objects would be attained by intraspinal injection of serum from persons already recovered from the disease, but such a procedure cannot yet be recommended in this disorder, partly because the presence of a neutralizing principle in convalescent blood has not yet been demonstrated and partly because the course of the disease is so prolonged that a very large number of injections would have to be given. Administration of hexamethylenamine by mouth is, on the other hand, always to be recommended, though its exact utility is still in doubt. Neosalvarsan injections seemed to do

harm in one case. Enlargement of the salivary glands and salivation having been noted in some cases, administration of jaborandi or pilocarpine to hasten elimination of the virus with the saliva is indicated. Adrenalin is always combined with it to antagonize heart depression by the pilocarpine, as well as to combat the asthenia commonly present in these cases and probably dependent upon fixation of the virus by the nerve cells of the endocrine organs. The measure most strongly advised by the author is the fixation abscess, instituted by injecting one or two mils of oil of turpentine in the outer aspect of the thigh. Hippocrates had already noted that in patients who recovered from *lethargus* a spontaneous abscess generally developed in some part or other of the body. Out of twenty-seven cases in which Netter injected turpentine, in nineteen an incisable abscess formed, and of these nineteen patients only one, a pregnant woman, succumbed to the disease, although fourteen of them had the myoclonic form of encephalitis, considered more deadly than other forms. Two patients out of the eight who did not form an incisable abscess succumbed before collection of pus had occurred, and the other six, in whom the turpentine had caused no local reaction, likewise succumbed. Out of twenty-five patients who received no turpentine injections, thirteen, or over fifty per cent., died. Fochier's theory that a fixation abscess draws away virulent matter from the general circulation to the point of injection has not been confirmed by experimental work, but the abscess does in some way yield benefit, probably by awakening a reaction in the organs in which the materials for defence against the disease are formed. Netter's pupil, Mozer, has shown, at least, that the bone marrow participates in the reaction, throwing out myelocytes into the blood stream.

Treatment of Pelvic Infection.—Theodore J. Doerlein (*Surgery, Gynecology and Obstetrics*, June, 1920) emphasizes the following points in the classification and treatment of types of pelvic infections:

1. The classification of pelvic infections into ascending and descending is not merely academic but of practical value for better analysis of the cases, especially with regard to prognosis.

2. Operations for descending pelvic infections are rarely connected with grave danger, once the infection has reached the quiescent or elective period.

3. One should seek to make a differential diagnosis in the ascending type, i. e., between puerperal and gonorrhoeal infections, before operation, as the prognosis depends on proper diagnosis.

4. Judicious conservatism is productive of best results.

Röntgen Ray Treatment of Surgical Tuberculosis.—Hans Iselin (*Schweizerische medizinische Wochenschrift*, June 17, 1920) says that as a chronic infectious disease surgical tuberculosis is not suited for radical operative treatment, even though the extirpation of a single primary focus might be an ideal procedure. He extols the value of the röntgen rays as being preferable in the treatment of this disease.

Miscellany from Home and Foreign Journals

New Laws Relating to Inherited Syphilis.—Carle (*Presse médicale*, April 24, 1920) notes that, according to the law of Colles, a syphilitic child procreated by a syphilitic father generally does not infect the apparently healthy mother, who may nurse the child without risk. This law, thus worded, should be abandoned as subject to erroneous and dangerous interpretation, and should be replaced by the following: A mother giving birth to a syphilitic child who exhibits secondary manifestations of syphilis soon after birth is always syphilitic herself, even if apparently healthy; she may therefore nurse the child in safety, but should be at once subjected to specific treatment which should thereafter be systematically continued. Profeta's law is as follows: An admittedly healthy child born of a syphilitic mother cannot contract syphilis through being nursed or through any other contact with her; such immunity is not perpetual. For this wording Carle would substitute the following more comprehensive statement: A child born of a syphilitic mother is himself generally syphilitic, in spite of his apparent normal condition at birth; he therefore has every chance of not being contaminated through lactation; this is not an absolute rule, however, and all children born under such conditions should be carefully watched, and the Bordet-Wassermann reaction carried out if possible before they are declared to be healthy. As a corollary to Profeta's law the author would state that the manifestations of so-called late inherited syphilis are only the tertiary expression of ordinary congenital syphilis, the secondary symptoms of which, manifested in the usual way in the course of the first few years of life, have been overlooked or otherwise diagnosed. There is no such thing as late inherited syphilis, but there are late symptoms of an overlooked inherited syphilis. The third law, that of conceptional syphilis, is to the effect that syphilitic fetus in utero may, through the placental vessels, contaminate its mother, in whom there may appear in the course of pregnancy secondary manifestations, without there having ever been noted any primary manifestations. Evidence tending to substantiate this law is practically nil. Blood analyses have plainly shown that where two of the three parties are infected with syphilis, the third is likewise infected. The syphilitic pregnant woman has in all likelihood contracted her infection in the usual way, the chancre having, however, been overlooked—a common occurrence in the female sex. The so-called law of conceptional syphilis should be deleted from our textbooks.

A New Pylorus.—G. Gore Gillon (*Practitioner*, June, 1920) says that when one sets about altering the mechanism of the alimentary tract it behooves him to do so in a manner that will produce no secondary liability. When we want to do away with the old pyloric gateway we must make certain that the new gateway is situated at the lower end of the stomach, and by a jejunojejunostomy some three and a half inches away from the new pylorus we can make sure that the food stream does not

mingle with the bile and pancreatic fluids till the proper time. He holds the no loop operation to be physiologically incomplete; the bile and pancreatic fluids find their way into the stomach, and he believes that the subsequent complaints are due to this result, while after the operation he describes digestion goes on naturally. He thus describes his operation: After opening the abdomen and exposing the part of the stomach required, he put in his right hand and brought up from the left of the spine ten inches of jejunum, counting from the duodenojejunal junction, immediately at the left of the second lumbar vertebra; three inches of this proximal loop were used to make the first anastomosis, leaving seven inches for the second. The gastrojejunostomy opening is made three inches in length. He and his assistant now change their gloves and then make the anastomosis between the two descending legs of the jejunum at a distance of three and one half inches below the stomach opening. The anastomotic opening itself should measure one and a half inches vertically. The gastrocolic omentum is attached to the jejunum near the stomach by two stitches, and any veins in the omentum tied. The abdomen is then sewn up in the usual way. The patient can lie in a recumbent position a few hours after the operation and need not be propped up; hence there is less strain on the abdominal stitches. He is fed with tablespoonfuls of water for a day, then peptonized milk in the usual way for a few days, and in a week is taking a fair amount of light food. On the twelfth day he gets two or three grains of calomel; prior to that his bowels are opened by rectal injections if required. He should lie on his back for the first three weeks and leave hospital on the 24th to 28th day. He claims that the results are uniformly good and that the patients are not only well, but very well. They put on weight and acquire a great capacity for swallowing large quantities of liquids without discomfort.

Lethargic Meningitis, Meningoencephalitis, and Encephalitis.—Bériel and Branche (*Lyon médical*, March 25, 1920) state that they have been struck by the occurrence, during the past year, of an unusual number of infectious states with special involvement of the nervous centres and presenting all intermediate types from radiculitis to radiculomyelitis, meningitis, and meningoencephalitis. By their consentaneous occurrence and curability these cases seemed to be allied. The most pronounced cases simulated tuberculous meningitis in their subacute course, cerebrospinal fluid reactions, temperature curve, and admixture of meningeal and encephalic manifestations, but recovery took place. Lethargic encephalitis is but a single peculiar expression of an infection of the nervous centres that may appear in various localizations, though doubtless due to a single, as yet unknown, cause. One patient presented violent myoclonic seizures, and death took place in a continuous epileptoid paroxysm; the autopsy showed, histologically, a diffuse meningoencephalitis.

Effects of a Serum Precipitin on Animals of the Species Furnishing the Precipitinogen.—Peyton Rous, George W. Wilson, and Jean Oliver (*Journal of Experimental Medicine*, March, 1920) attempted to determine whether serum used as antigen gives rise to injurious principles in the anti-serum, as the serum of infected individuals would form a convenient antigen in many diseases. They found that there is present in serum of high precipitin titer, which was produced by the repeated injection of rabbits with the blood free serum of guineapigs or dogs, a principle highly toxic for animals of the species furnishing the antigen. After intravenous injection of the serum severe shock or sudden death occurred, and there were produced locally acute inflammatory changes and profuse capillary hemorrhages. The serum was exposed repeatedly to washed red cells to remove the hemolysins and hemagglutinins with only a slightly lessened toxicity resulting, and the removal of precipitin by specific precipitation *in vitro* had no detoxifying effect. The symptoms produced in guineapigs and dogs after intravenous injections of the treated and untreated sera were similar to those of anaphylaxis, but attempts at desensitization failed. It must still be determined whether the toxic principle is a hitherto unrecognized antibody, or a toxic product of the interaction of precipitin and precipitinogen. Evidently the fluids of infected human beings cannot be practically utilized for the production of anti-serum unless the obstacle of the presence of the injurious principles can be somehow overcome.

Orthostatic Cardiac Acceleration of Abdominal Origin.—Préval (*Presse médicale*, April 21, 1920) believes that acceleration of the heart rate upon rising from the recumbent to the standing position is an abnormal and not a physiological phenomenon. It is due generally to disturbed equilibrium of the abdominal organs, particularly the stomach, and is the result of a reflex mechanism in which probably participate the gastric branches of the solar plexus. This reflex may be clinically demonstrated by the application of a hypogastric belt, which causes the orthostatic acceleration to disappear when it is dependent upon gastroptosis. Orthostatic cardiac acceleration may and should be treated by better hygiene of the stomach and by physiological reeducation of the abdominal wall. Such treatment is especially necessary where there is tachycardia on exertion, a condition often partly due to the operation of the abdominocardiac reflex.

Availability of Carbohydrate in Certain Vegetables.—W. H. Olmstead (*Journal of Biological Chemistry*, January, 1920), by the use of diastase and copper reduction, and by feeding to phloridzinized dogs, determined the sugar forming material in certain vegetables which are commonly used in dietaries of diabetics. Nearly all the carbohydrates may be washed out of the vegetables by cooking. Cabbage showed 4.4 per cent. of available carbohydrate or glucose by the takadiastase method, and five per cent. by the phloridzinized dog, while thrice cooked cabbage showed corresponding figures of 0.4 and 0.5 per cent. Cauliflower by the diastase method gave 2.8 per cent. of available carbohydrate, and thrice cooked cauliflower 0.8 per cent.

Spinal Analgesia.—A. E. Halstead (*International Journal of Surgery*, April, 1920) asserts that the indications for the use of spinal analgesia are in general: 1, Those cases where for any reason a general anesthetic is not considered safe, e. g., in intestinal obstruction with fecal vomiting. In general peritonitis, for the same reasons. Also in strangulated hernias, and in operations in old people, such as prostatectomy. 2, In traumatic surgery of the lower extremities, in crushing injuries. The solution injected into the spinal canal not alone produces analgesia, but in doing so also blocks the sensory tracts of the cord and lessens shock. 3, In disarticulations of the hip or in high amputations for conditions not depending upon trauma. These operations can be carried out with much less shock than if a general anesthetic is employed.

Letters to the Editors.

SEX GLAND IMPLANTATION.

CHICAGO, August 10, 1920.

To the Editors:

The public press of this country recently has been flooded with articles regarding the alleged work in sex gland implantation of Dr. Serge Voronoff of Paris. The *New York Tribune* of July 19, 1920, quoted him as saying that he had concluded that human glands were preferable to ape glands, which he had been using. He also said that glands from electrocuted criminals and from bodies dead of accident were available sources of material. He further said that if the New York profession would furnish patient and material, he would teach them how to do the work. How a man of Voronoff's scientific training could have overlooked my work I cannot understand. In the *Bulletin of the Chicago Medical Society*, March 7, 1914, and *NEW YORK MEDICAL JOURNAL*, March 21, April 4, July 11, October 17-24-31, and November 7, 1914, I published a large series of cases of human implantations of testes and ovaries taken from dead bodies. Most of these cases were successful. I made sections of implanted glands showing the hormone producing cells and new blood vessels. I have done up to date a large number of implants with most astonishing results as to rejuvenation and effects on various bodily functions. I also have done some animal experimentation. Some of my later work was published in the *Journal of the American Medical Association*. My work antedated any claims of Voronoff by six years. I challenge Voronoff to show that he has even seen, much less performed, a single human testicle or ovarian implant up to date. In his book, published this year, not a single such case is recorded. Why is it that the press of this country exploits foreigners who have done nothing and ignores the work of American workers, who have done much? And when will the chauvinistic foreigner discover America? I expect at any moment to learn that some foreigner has just written the Constitution of the United States or discovered Cape Cod.

Very fraternally,
G. FRANK LYDSTON, M. D.

FRACTURES OF THE LONG BONES AND THEIR REPAIR.*

By ETHAN H. SMITH, M. D.,
San Francisco.

The type of fracture of any long bone has much to do, first, with the matter of reduction, second, with the healing of the fracture. Formerly we were taught to fear oblique fractures. Since the common use of the radiograph we find that but relatively few fractures are strictly transverse. We also find that the transverse fracture, when displaced, is likely to be difficult to reduce. This is because the muscles will not stretch without great force beyond the normal length of the part of which the bone is a portion. Oblique fractures slide readily into place with, perhaps, a shortening so slight as to be of no consequence.

Longitudinal fractures if not widely separated or complicated by more or less transverse fractures can usually be replaced without much difficulty. When complicated as mentioned, they are as a rule most difficult to replace. Comminuted and multiple fractures are always difficult to handle, both as to replacement and securing union. Open fractures are always to be regarded as presenting problems to be handled one at a time as each one occurs. Only general rules can be laid down, but these few rules are well nigh absolute if we are to expect success.

Gentle handling of all fractures is an absolute necessity if we wish good results. Rope and tackle, Hawley tables and such paraphernalia are a retrogression of a century at least in handling fractures. They substitute unnecessary brute force and thoughtlessness for skill and intelligence. To reduce fractures, all muscles concerned in the fracture must be relaxed. This can not be done by putting a portion of them on the stretch as is done by the rope and tackle or the Hawley table. Recent fractures, gotten quickly in the hands of the surgeon, rarely present great difficulty in reduction. Great swelling, huge extravasation of blood or rapid edema of the muscles may make reduction difficult. Any or all of these conditions make forcible reduction a reckless procedure. Increased hemorrhage and the probable rupture of muscular fibrillæ are to be expected from such work. More than that, they increase the difficulty of retaining the fracture in

apposition and increase the tendency to slough. Pain afterward is also augmented and unnecessarily so.

In the repair of bone new material is thrown out between the periosteum and the shaft of the bone and also from the medulla through the cancellous portion of the bone. Some reparative material is thrown out over a goodly portion of the broken surface providing the circulation has not been too seriously impaired. The periosteum does not form bone. It limits its formation and protects the bone. Strip the periosteum off a portion of the sound bone and prevent infection, and an exostosis will form which will be limited when again covered by the repair of the periosteum. Periosteum stripped loose from the shaft of bone will many times heal back in place, but it will never adhere to the end grain of cut or broken bone. An oblique fracture makes a quicker repair than a transverse fracture. There is a much larger surface to furnish material for repair, and the union does not have to be so complete in order to support the broken parts.

A notch out of the cylinder of the shaft of a long bone, due to a widely displaced small fragment, makes an awkward fracture to handle. The time required to fill in the space due to this displaced fragment may be so long as to prevent the calcium salts from being deposited and lead to a partial fibrous union. Widely separated fragments undergo the same process quite often.

In delayed union or nonunion, we have the ends of the fragments united by preliminary soft tissue. This if not reinforced by the mineral salts soon partakes of the nature of scar tissue, coats over the broken surface and blocks out the mineral salts. The ends of the fragments become sclerosed and harder than normal. Operating on these adjacent ends of bone and merely fastening them together by any device whatsoever, is a waste of time and a reckless surgical risk. We must go above and below the fracture into normal bone and open up a channel through which reparative material may be brought in to complete the union. Do not cut into or through excessively denuded, bruised or lacerated tissue to reach a fracture in operating upon it. Wait until the soft parts have recuperated. "Haste makes waste" in many illadvised operations on fractures.

All metal contrivances for the repair of bone are bad, and if used at all are to be regarded as a choice between evils. They are seldom required

*Read before the North Western Pacific Railroad Surgeons Association, April 24, 1920, San Francisco, California.

at all. The plate is one of the worst of all inventions. It does more harm than good, is a weak device, and has been largely discarded in the operative treatment of bone. Staples are justly obsolete and never should have been used. Silver wire has a limited use, and is valuable occasionally, not because it is silver, but because it is pliable and can be pulled into place and cannot bear enough strain to do much harm by cutting through the bone, thus hindering repair.

Kangaroo tendon offers the best material for binding fractures in place, but requires perfect technique to prevent infection. If it is infected it makes a bad mess. It should be placed in 1:1000 bichloride of mercury solution, not for the antiseptic effect of the solution, but to render it readily pliable so that it can be accurately placed and tied.

BONE GRAFTS.

Do not put in an intermedullary bone graft. It fills up the medullary canal and prevents restoration of the intermedullary repair and nutritive circulation of blood in the bone. It prevents a sufficient deposition of callus and often prevents union of the fractured shaft. The graft unites within the medullary canal leaving only the graft itself at the site of fracture. Refracture is sure to follow. It also frequently causes a throbbing pain at the site of fracture until the medullary canal is cleared of obstruction. In case of refracture it must be removed before union can take place as the result of further operative procedures.

Do not take a graft from the crest of the tibia. The bone is too compact and does not readily unite with the less dense bone into which it is inserted. It does not allow of the necessary flow of reparative material to the site of fracture. It leaves a damaged tibia that will not make a good repair.

Do not reverse the longitudinal axis of a bone transplant in taking it from one position to another. If you do, you will reverse all the nutritive channels within the transplant and perhaps have the transplant perish and the operation fail.

Never try to use damaged bone for a transplant. It will perish every time. Fit the transplant accurately into a carefully prepared seat. Do not jam it too tightly into place. Do not bruise or batter any of the bone. Do not place it in any solution. Do as little handling as possible and place it in site as quickly as possible. Do as little trauma as possible in handling any part of the work.

Do not leave periosteum on a bone peg to be placed within the bone as in the neck of the femur. Do not place a bone transplant in the central axis of the femoral neck, as it will lie in a bed composed largely of fat, which is a semimedullary tissue and the transplant will be wasted. The upper portion of the femoral neck is the most advantageous site for the transplant. Remember that the adult femoral neck from the greatest convexity of the trochanter major to the attachment of the ligamentum teres, is from three and three eighths inches to three and five eighths inches in length. It is never necessary to turn a round peg for this transplant. Use a quarter or three eighths inch bone chisel, graduated in quarter inches on one side. Cut a square hole in the shell of the trochanter. Gently

drive the chisel into the neck, loosening it gently from time to time. Drive it in about three inches in the adult bone. Lay the chisel bit on the anterior wall of the shaft of the exposed tibia and mark out a three and one quarter inch long transplant, the width of the chisel bit, with a scalpel. Saw out the graft right into the medullary canal. Gently detach it after sawing a point on the lower end. Carefully shave off the medullary tissue and strip off the periosteum and shove it home through the previously prepared chisel hole. Nip off the short protruding end and the job is neatly and quickly done. This method does away with an unsafe machine that cannot be well sterilized, prevents unnecessary trauma, preserves the vitality of the transplant and saves valuable time.

In fracture of the neck of the femur, when the line of fracture is near the head of the bone, replacement of the fragments is more difficult than when the fracture occurs nearer the trochanter. If the ligamentum teres is ruptured, thus destroying the artery which enters the head of the bone at the attachment of the ligament this fragment may be rapidly absorbed. Bony union between the fragments is also doubtful. If there are two lines of fracture, one near the head of the bone and one near the trochanter, the intervening fragment may absorb leading to fibrous union, or in fortunate cases a very much shortened neck of the bone. Whether or not the fracture is intracapsular or extracapsular has practically nothing to do with the healing of the bone, except that it makes a difference in the adjustment of the fracture. The disturbance of the blood supply is the controlling factor in the matter of repair, providing we know how to treat the fracture.

The terms intracapsular and extracapsular are rather ridiculous as usually applied to the neck of the femur. As an anatomical fact the neck of the femur is wholly intracapsular, except a small triangular portion near the digital fossa, posteriorly situated.

If an overriding fracture of the shaft of a long bone cannot be reduced by careful manipulation under an anesthetic, do not attempt to make a forcible reduction by means of ropes and pulleys, or a machine like the Hawley table, as you will do infinite harm to the soft parts. Although you may apply plaster of paris with the parts on the stretch while in position on the table, there is no certainty of the bone remaining in place when the patient is released from the table. The pain afterwards is unjustifiable. Pressure sores are common. Paralysis of the bladder has occurred and persisted for an indefinite time from the pressure on the perineum, the forcible reduction of fracture of the femur by means of the Hawley table. A much easier and by far better method is to make an incision, and by use of the simple device known as a bone skid, the fracture can be reduced quickly and easily and without harm. The part can then be put up in appropriate dressings with the muscles relaxed and with the certainty that the patient is not going to suffer unnecessary pain.

Bones cut smoothly and transversely to the long axis of the shaft unite slowly or perhaps not at all

even in the absence of any deleterious influence. Bones cut obliquely or longitudinally and spliced in that manner will unite very quickly under favorable conditions. One reason for this is that in the latter condition much wider surface is exposed and on account of the peculiar structure of the bone, larger nutritive channels are opened up, through which bone building material can be brought to the site of union.

Do not attempt reparative work on open fractures until after the soft parts have healed and all infection, latent or active, has ceased. Do not plate these fractures. Do not operate on any fracture under a week or ten days unless it is the patella, which may sometimes be sutured in five days. You invite infection by too early operation. By waiting, much extravasated blood is absorbed, many blood vessels have been restored and the lymph spaces occluded, rendering the operation nearly as safe as a clean operation on the soft parts. Otherwise, infection is the rule.

Never undertake to do a bone graft or operative repair of any fracture when there is pus in the wound or necrosed bone or active or latent infection in the tissues. That is an invitation to the most destructive infection with possible loss of life or limb. It certainly means a failure as far as repair of the fracture is concerned.

Do not use an unnecessary piece of catgut in fracture work. Heavy hemostats left in place for a few minutes will stop hemorrhage from small vessels and prevent infection from too much catgut. Bones and ligaments do not readily dispose of catgut.

Most fractures of the femur can be treated with absolutely satisfactory results by the modified Hodgen splint or by weight and pulleys and long sand bags.

Never use any sort of zinc oxide adhesive plaster for traction. It is not strong enough. It wrinkles and makes sores. It is irritating to the skin and is a most unsatisfactory material. Most surgeons use whatever adhesive material is handed them. Shiver's moleskin adhesive plaster is the only material fit to use for this purpose. This statement may not get much consideration, but Sayre would never have made the great record he did without moleskin adhesive plaster. He was absolute in his teaching on this point and he was right.

It is superlative folly for any surgeon to state that a fracture of the femoral neck cannot be successfully handled by straight traction and the proper use of sand bags. This method is vastly superior to all others if properly applied, better as to the safety and comfort of the patient, puts the bones in better apposition than any other method and gives unexcelled results. A small sand bag behind the trochanter is the factor added to the rest that keeps the broken surfaces from rotating apart. The method must be seen to be learned and moleskin adhesive plaster is essential.

All fractures of the leg, including fractures involving the ankle, should invariably be reduced with the knee semiflexed and never in the extended position. They should always be put on a splint or in plaster with the knee held in semiflexion and the thigh included to the hip in the dressing. This

excludes the Hawley table and obviates the use of brute force in handling these fractures.

Colles's fractures should be put up in a dressing including the arm so as to prevent pronation and supination. The fingers and thumb should be free and movement of the digits encouraged. Splints are bad as they cause clamplike pressure and favor adhesions. Tenosynovitis is all too common in these fractures. It happens in persons of all ages and by any method of treatment. Some biological product is liberated into the tissues in fractures near joints, causing adhesions and thickening of epiphyseal structures. Some day someone will explain what happens.

Do not do passive movements with joints when there is free movement between fractured parts near by. Pain and irritation and damage will result. Do not bake any bone or joint unless you want it for food. It means devitalization of tissue and permanent damage. Do not massage infected tissue until all infection has ceased.

Do not use sheet wadding under plaster of paris or to pad splints. It does not pad a part sufficiently. It wrinkles and makes sores. It irritates the skin. It stinks. It is unpardonably bad. Use a good quality of absorbent cotton.

Frequently large hemorrhages take place, sometimes deeply in the limb, sometimes under the cutaneous structures. In uninfected cases these hemorrhages rapidly form clots which are absorbed within a few days or weeks. The absorption of this blood, together with that escaping from the broken bone, often causes a rise in temperature of from one to several degrees. In compound fractures it makes us apprehensive as to whether the rise of temperature is due to this cause or to a beginning infection. A large clot of blood which is capable of being demonstrated should be carefully watched. Sometimes five or six or even more weeks after the occurrence of a fracture, even after the union of the bone, one of these large clots will begin to liquefy. Through a small opening, evacuate the broken down, liquefied blood clot, of course with strict surgical precautions. The liquefaction of the blood clot is evidence of infection which will certainly result in an abscess and widespread infection unless the disorganized blood is promptly evacuated. Place a wet compress, preferably one to two thousand solution of permanganate of potassium, over the part and bandage rather firmly. This will prevent refilling of the evacuated cavity.

701 PHELAN BUILDING.

Measurements of Goitre on the Living.—H. Hunziker (*Schweizerische medizinische Wochenschrift*, January 29, 1920) proposes as a standard scale of measurements by means of which the size of goitres in different regions and countries may be compared, the square area obtained by multiplying the breadth of the palpable thyroid by its height in centimetres. When the thyroid cannot be felt the record would be 0; when it is one cm. broad and one cm. high, the record would be one; measuring six by five cm. it would be thirty; measuring seventeen by twelve cm. it would be 204, and so on.

SPLENECTOMY, WITH REPORT OF TWO CASES.*

BY GEORGE I. MILLER, M. D.,
Brooklyn.

The rarity of articles on the diseases of the spleen and their treatment, compared with the legions of essays on other anatomical parts, invites interest and enthusiasm in the study of this mysterious ductless organ. Organs in the body richly supplied with blood vessels and lymphatics and not provided with ducts are necessarily regulators of the complex human mechanism. These organs exert this systemic influence through the blood stream. To what extent the spleen is of value to the body cannot be determined by direct studies, since the spleen has no external secretion and no known internal secretion, and, furthermore, the removal of the normal spleen causes no serious bodily change.

Historically, splenic surgery is of great interest. As early as 1500, spleens were removed from animals without affecting their health. Krumbhaar says Aristotle suspected that the spleen was not essential to life. In 1549 Zaccarelli was said to have removed the spleen from a patient, with satisfactory results.

The earliest splenectomy in this country was done by Browne in 1814, the patient living and remaining in good health after the operation. In 1866, Quittenlaum, Spence, and Wells (1) removed spleens not only in cases of injury, but also from patients suffering with constitutional disturbances and splenomegaly. The revolutionary period of splenic surgery, however, must be considered from 1894, when Banti (loc. cit., 77) described the disease which bears his name.

The operations performed on the spleen are mostly splenectomy, splenorrhaphy, splenopexy, aspiration, and splenotomy. Splenectomy is advocated in a great variety of diseases and conditions, especially when the spleen is enlarged to twice or more its normal size. Clinically, the enlargement of the spleen is to be considered the barometer of systemic disturbance, since the spleen itself is seldom the cause of the disease.

Physiologically, the spleen enlarges following food intake and resumes its normal size after several hours. This enlargement may be due to the influx of blood from the celiac axis, during the process of digestion, the same source which supplies the stomach, the duodenum, the liver, and the pancreas with blood. Enlarged spleens caused by disease show constant pathological changes, irrespective of the clinical phenomenon. The spleen, on examination, reveals marked fibrosis, degeneration of the blood vessels and malpighian bodies, or swelling, or atrophy of the splenic pulp.

Elliot and Kanel state that the intramuscular injection of epinephrine contracts the spleen one third the size.

The function of the spleen has not been definitely established. It is known to have phagocytic properties, to develop hemolytic ferments, to act as a

mechanical strainer, and to divert a large volume of blood from the general to the portal circulation. It also directs bacteria and protozoa, toxic products, and worn out red cells from the blood to the liver for destruction. The spleen, therefore, in health is to be considered a desirable organ, while under certain conditions in disease it proves to be an untrustworthy, dispensable traitor, causing destruction of blood ingredients, the loss of which eventually kills the patient. Its timely removal, therefore, stops the progressive destruction and the patient recovers.

Traumatism of the spleen may result in: 1, Subcutaneous rupture, usually produced by falls, kicks, or the passage of a wheel across the abdomen. Congenital syphilis predisposes to rupture of the spleen during birth. 2, Open wounds of the spleen such as are caused by stab wounds and gunshot injuries. 3, Accidental injuries of the spleen have occurred by a trocar thrust into the abdomen for the relief of ascites or by a trocar thrust into the chest for empyema. The symptoms pathognomonic of injury of the spleen will be illustrated by the following case.

April 3, 1919, I was summoned in great haste to a private hospital, by a surgeon. He asked me to explain the collapsed condition of his patient, R. S., a married woman, forty-five years of age. She had been sick in bed about four weeks with pneumonia, followed by empyema. The physician had decided to treat the patient by introducing a large cannula into the chest and leaving it *in situ* for continued drainage, instead of by an open operation. About three hours before my arrival he thrust the cannula in the axillary line of the left ninth intercostal space. The patient experienced considerable pain and shortly afterward collapsed. I found her in bed, looking very pale, her lips were white, and the pulse was faintly perceptible. Abdominal percussion revealed dulness in both flanks. She showed all the evidences of abdominal hemorrhage.

I suggested a laparotomy, and on opening the abdomen we saw a typical picture of a ruptured ectopic gestation. After removing about two quarts of fluid and clotted blood, I demonstrated a ragged rent in the convex surface of the spleen, caused by the thrust of the cannula. I repaired the torn spleen with two mattress sutures and closed the abdomen. I transfused the patient, while she was still on the table, with 500 c. c. of whole blood. She made an uneventful recovery.

Movable and ptosed spleens can be anchored in position, except when torsion and strangulation of the pedicle have taken place; then splenectomy is indicated.

Maclaren relates the case of a woman, aged fifty-one, who suffered from palpitation, dyspnea and depression. The examination revealed an irregular tumor in the pelvis. Operation showed the tumor to be a wandering spleen with two complete turns in a pedicle ten inches long. Johnston collected eighteen cases of ectopic spleen from 1900 to 1908. MacDonald and Mackay, Solieri, Paterson reported cases of spleen in the pelvis, with acute torsion of the pedicle. In all cases splenectomy was performed with recovery. Benign growths and non-parasitic cysts of the spleen have been resected by

*Read before the Clinical Society of the People's Hospital, N. Y. City, February 11, 1920, and before the Kings County Medical Society, April 20, 1920.

Bircher. Splenectomy, however, proved to be the safer operation. A lymphangioma of the spleen was removed by R. H. Fowler. A case of multicystic spleen removed by splenectomy by Coenen was considered by him of lymphangiectatic origin. Johnston reported twelve cases of splenectomies for sarcoma with three recoveries. Bush recorded the case of a man whose spleen showed some whitish elevations on its surface suggesting sarcoma. Splenectomy was performed with recovery from the operation, but the patient died a few months later from metastasis.

Tuberculosis of the spleen.—Burke, in 1889, was the first to remove the spleen for splenic tuberculosis. Cases of splenectomy for primary tuberculosis of the spleen have been collected by Fisher showing twelve cases with four recoveries. W. J. Mayo reported a case of probable tuberculosis of the spleen, that of a young girl who died six months later from generalized tuberculosis. Bland Sutton believed tuberculosis of the spleen to be secondary to tuberculous foci elsewhere in the body. The spleen is frequently involved in children who die from tuberculosis.

Syphilis of the spleen.—Syphilitic spleens have been removed, with remarkable results, from patients who failed to improve under persistent anti-syphilitic treatment with salvarsan, neosalvarsan and mercurial remedies. The removed spleens showed encapsulated spirochetes. Splenomegaly is common in syphilitic children and is considered second in frequency to rickets. Gummata of the spleen are rare in both children and adults. Giffin in 1916 reported 6 cases of syphilitic splenomegaly showing marked anemia, a positive Wassermann and failure to improve under antisyphilitic treatment. The patients had changes in the liver and one patient had a gumma. Splenectomy, by removing the spirochetes within the organ, cured the patient.

Malarial spleen.—The removal of the spleen for chronic malarial splenomegaly is not generally recommended, although Finkelstein and Jonesco and others performed splenectomy with gratifying results.

Splenic anemia and Banti's disease.—Splenic anemia with splenomegaly and leucopenia is a chronic intoxication of unknown cause occurring in children and adults; at times in one third to one half of the cases it is accompanied with hemorrhage, especially from the stomach, and often terminates in Banti's disease with cirrhosis of the liver, jaundice and ascites. Balfour states that forty-two patients showing this type of disease were operated upon in the Mayo Clinic up to May, 1917. Splenomegaly usually preceded the anemia. The weight of the spleen in some of these cases has been increased from the normal 195 grams to 5,280 grams (Giffin). The enlargement was due to thrombophlebitis of the splenic and portal veins which occurred as a primary condition. Banti's disease is considered the advanced stage of splenic anemia—cases which have cirrhosis of the liver with ascites.

A. G. Gibson offers triple evidence that the disease is of parasitic origin: Splenectomy cures or alleviates the condition, the disease simulates

kala azar, and salvarsan acts beneficially. The pre-ascitic stage lasts several years. Gastric disturbance, abdominal pain, pallor and increasing weakness may be the attracting clinical symptoms. There may be a slight leucopenia and increased urobilin. As the disease progresses, the urine is diminished, high colored, with excess of urobilin. There may be diarrhea. Finally, cirrhosis of the liver and ascites are present. Some jaundice and emaciation can be observed. Splenectomy is a specific remedy in whatever stage of the disease the patient is found.

I operated in the following two cases belonging to this group:

CASE I.—G., D., aged forty-eight years, Russian. Admitted to the Jewish Hospital, Brooklyn, N. Y., September 8, 1915, and discharged October 8, 1915.

Family history, negative. Previous personal history, married twenty-eight years. Gave birth to six healthy children; never aborted; menstruation regular. Had typhoid fever at the age of twenty. For the past eight years she had had myalgia.

Present illness: Six years ago she was admitted to the Vienna General Hospital for pain in the abdomen and left side. She remained in this institution for four weeks and left feeling well. She arrived in America two years ago. Six months previously the patient noticed a hard mass in the left hypochondrium, which gradually increased in size. Two months before admission to the hospital, she had an attack of abdominal cramps which lasted twenty-four hours. Since then she had felt a sensation of weight and a sticking pain in the left side of the abdomen. She did not cough or vomit. She had lost about fifty pounds in weight in the past eight years.

Physical examination, adult female; well developed; anemic; not dyspneic; appeared chronically ill. There were no glandular enlargements. The abdomen showed a firm mass in the left side, extending from the tenth rib to the pelvis and to the linea alba anteriorly. The mass was somewhat tender. There were varicose veins of legs. Reflexes normal. Temperature, 101°; pulse, 100; respiration, 20.

Urine examination, specific gravity, 1020; acid; negative. Blood examination, red blood cells, 3,260,000; leucocytes, 7,400; neutrophils, 61; lymphocytes, 34; mononuclears, 3; basophiles, 1; eosinophiles, 1; hemoglobin, 70 per cent.

Operation, September 20, 1915. Ether anesthesia. Left upper rectus incision, peritoneum opened. Adhesions above and to left of the spleen separated without difficulty. Spleen delivered; ten by six inches in size. Pedicle tied with double ligature and cut. The spleen was removed. The abdominal wall was closed. Immediately following the operation, I transfused 350 c. c. of unmodified blood. Four to five accessory spleens, about the size of walnuts, were present. The patient made an uneventful recovery and has since gained about twenty pounds in weight and is in perfect health. She has been absolutely cured by the operation.

CASE II.—H. K., real estate, aged sixty-four years, Russian; lived in New York forty years. He

had eleven healthy children. His wife never aborted. The patient entered the Jewish Hospital of Brooklyn, October 9, 1919, for the relief of weakness, pallor, loss of weight and a large mass in the abdomen. The family history was negative.

Previous personal history: Had typhoid fever thirty-eight years ago; had had no malaria or syphilis. The patient suffered from chronic articular and muscular rheumatism for several years prior to ten years ago. He was never subject to colds or tonsillitis; never had gallstone colic or abdominal pain. His cervical, axillary or inguinal glands were never enlarged. The patient lost his left eye forty-three years ago from a bullet shot. His habits were good; occasionally drank several glasses of prewar beer. Denied venereal disease. Slept well; appetite good until four months ago; constipated.

Present illness: Four months ago the patient noticed a painless mass in the left side of his abdomen. In the course of a few weeks the mass grew much larger. He lost about twenty-five pounds in weight since he became sick and noticed a progressive loss in strength and marked pallor. He had no nausea or vomiting. No gastric hemorrhages or blood at stool. The patient consulted several physicians and was treated medically with large quantities of liquids, powders and pills without relief. He went to the Catskills for three weeks, which seemed to have improved his strength and color. The abdominal mass, however, remained the same size. On returning to the city he was referred to a specialist on internal diseases, who informed him that his spleen was enlarged, and recommended x ray treatment. He received seven x ray exposures at intervals of four days, each exposure lasting from fifteen to twenty minutes. After the first four exposures the spleen seemed to have shrunk to about one half the size, but later became even larger than before the treatment. He was then advised to have his spleen removed.

Physical examination showed an elderly man, five feet, five inches in height, with sallow skin, anemic, pale; left eye missing; right sclera not jaundiced; pupils normal. The patient was lying in bed. He appeared chronically ill. Most of his teeth were missing. Those remaining were carious and loose; tongue was coated; tonsils, negative; neck, symmetrical; no glandular enlargement; the skin was faintly jaundiced. There was no pruritis, no blebs, and no pigmentation. The heart was not enlarged. There was a faint systolic murmur at the apex, which was transmitted toward the left axilla. There was no angina. The pulses were of small volume and low tension. The arteries showed moderate thickening; somewhat tortuous. The lungs were negative. He did not cough; was never dyspneic or cyanotic. The abdomen showed a slight fulness in the flanks and shifted with change of position. The liver edge was felt two inches below the costal margin. The spleen filled the entire left half of the abdominal cavity, extending from underneath the left costal margin to the left iliac fossa and to the right of the linea alba. The glands of the groin were not enlarged.

Patient admitted to the Jewish Hospital, Brook-

lyn, October 9, 1919. Temperature, 101° F.; pulse, 104; respiration, 24; blood pressure, 130 systolic; 78 diastolic. Blood examination, red blood cells, 3,328,000; white blood cells, 3,000; polymorphonuclears, 64; lymphocytes, 36; hemoglobin, 55 per cent. The Wassermann was negative; urine examination, specific gravity, 1,015; hyaline and granular casts, few pus cells.

October 10, 1919, I gave him a blood transfusion of 400 c. c. of whole blood. October 13, 1919, blood examination showed red blood cells, 3,808,000; white blood cells, 3,200; polymorphonuclears, 70; lymphocytes, 30; hemoglobin, 65 per cent.

October 20, 1919, I gave him a second blood transfusion of 400 c. c. of whole blood. The blood examination showed, red blood cells, 3,840,000; white blood cells, 3,200; polymorphonuclears, 61; lymphocytes, 30; hemoglobin, 65 per cent.

October 22, 1919, under gas, oxygen and ether anesthesia, in the presence of a number of surgeons who attended the Congress of the American College of Surgeons, I opened the abdomen of the patient by making an incision in the linea alba, from the ensiform cartilage down to two inches below the umbilicus. On opening the peritoneum I evacuated about six ounces of serous fluid. The liver was smooth and extended three inches below the normal line. The gallbladder and appendix were normal.

The spleen filled the entire left portion of the abdominal cavity. It was smooth and hard. Extensive adhesions bound it firmly to the diaphragm, to the parietes and to its own bed. The adhesions were easily destructible so that I succeeded in breaking through them, without injuring the spleen. I enucleated the organ by lifting the lower extremity through the incision and then the middle and upper part until it was entirely out of the abdominal cavity. The spleen was then turned over to the left, which exposed the internal surface and its pedicle. Without much traction on the pedicle, I divided it between two ligatures. I clamped and ligated the splenic vessels. After breaking up the adhesions and before removing the spleen, I packed several abdominal pads in the splenic bed to prevent hemorrhage. These pads were removed and the splenic bed and the pillar of the diaphragm inspected. Bleeding from the oozing points had stopped. There were no mesenteric glandular enlargements. The stomach and intestines were normal.

The abdominal wall was closed by four layers of sutures, without drainage, using bolsters, silk-worm and silk for the skin. The dressings were compressive and elastic so as to fill up the void left by the removal of the spleen. While still under the anesthetic, I gave the patient a postoperative blood transfusion of 500 c. c. of whole blood to overcome the shock, to increase his resisting power and to return the blood he had lost. Time of both operations, forty minutes.

The following day the patient appeared bright and cheerful and showed no sign of reaction. He had no chill. Temperature, 101°; pulse, 110; respiration, 24. During the second night he was restless; slept at intervals. Temperature, 102°; pulse, 130; respiration, 28.

October 24, 1919, I gave him the fourth blood transfusion of 400 c. c. of unmodified blood. From that day on he showed signs of gradual improvement. The suture line had to be opened on account of a stitch infection. Eleven days after operation he was in a wheel chair on the porch, and every day thereafter, the weather permitting.

Blood examination, November 1, 1919, red blood cells, 4,200,000; white blood cells, 8,000; hemoglobin, 65 per cent. November 6, 1919, temperature, 100°; pulse, 90; respiration, 20. During the early morning of November 7, 1919, he suddenly had a copious intestinal hemorrhage of venous blood. November 9, 1919, he had several hemorrhages from the bowel which exhausted him. The pulse became soft and empty. He was drowsy and muttering, but could be easily aroused by loud questions. He complained of no pain. November 10, 1919, he became unconscious and remained so until he died the following day. No autopsy was held. The spleen weighed five pounds and was smooth and hard.

Histologically, it showed no perivascular inflammation or thickening. There was no increase in interstitial fibrous tissue. It did show lymph granuloma denoting evidence of Hodgkin's disease.

Osler (2) states, "In Hodgkin's disease, whether or not there is a type involving the spleen alone without the lymph glands, is still a question. The disease may originate in the lymphoid tissues of the spleen. It is very difficult to distinguish such cases clinically from the early stages of Banti's disease." Pool collected four cases of splenectomy for the anemia of von Jaksch. Considering the fact that from a third to a half of the cases of splenic anemia have gastrointestinal hemorrhages without evidence of existing ulcer in the stomach or the duodenum, and that the removal of a small or slightly enlarged spleen from a patient with obscure gastric hemorrhage cures the patient, we are justified in believing such patients to be victims of unrecognized cases of splenic anemia.

Therefore after excluding every causative lesion which may cause gastric hemorrhage and bearing in mind the fact that the spleen is the root of infection which gives unaccounted toxic hemorrhage, I believe that such cases should be considered splenic anemia *per se*.

Hemolytic jaundice.—Nonobstructive hemolytic icterus with anemia and splenomegaly may be the congenital familial type of Minkowski and the acquired type of Hyam and Widal. The blood in these cases shows increased fragility of the red blood cells, which is to be considered the most important diagnostic sign. Bile pigment is also constant in the blood and urobilin in the urine.

Elliot and Kanavel were the first to report splenectomy in this disease in 1915. Nineteen cases of hemolytic icterus operated on in the Mayo Clinic are reported with gratifying results. The jaundice which existed for years disappeared within four days. About sixty per cent. of these cases had complicating gallstones due to thickened bile, the result of pigment derived from the disintegrated red cells. The patients showed chronic jaundice of a mild degree, not accompanied with itching or the clay

stools usually associated with jaundice due to obstruction of the common duct. Bile is always present in the stool. The spleen and liver were usually enlarged and often painful. Anemia was present. The patients with congenital and acquired types suffered more and were more likely to seek relief.

Minkowski, Eppinger, and Banti believe that the spleen is the destroying agent of the red cells and the fact that the removal of the organ cures the patient is convincing evidence to support this view. The reported cases of splenectomy in this disease with uniformly excellent results must be looked upon as a therapeutic measure well warranted in every case of the congenital and acquired type.

Pernicious anemia.—The removal of the spleen in cases of pernicious anemia effects a remission of symptoms to some extent. Percy suggests the removal of the gallbladder and the appendix as additional possible foci of infection which may be the causative factor of the disease. There is, however, thus far, no proof that splenectomy will cure the disease or permanently check the symptoms. The operation has proved of empirical value when performed early in the disease and before destructive changes have taken place in the cord. The anemia of the pernicious type is due to destruction of the red blood cells and not to inhibition of blood formation, and in the absence of any other evidence as to the cause of this destruction, the enlarged spleen should be considered a crematory, which, when removed in time, proves to be the best therapeutic remedy at our command. Its removal is followed by absolute improvement if not by actual cure.

Leucemia.—In splenomedullary leucemia, radium, the x ray and benzol temporarily exert specific effects on the spleen and on the blood picture, but remissions occur. The spleen under radium treatment is often reduced to a nonpalpable, normal sized organ and disappears behind the left costal margin. The several hundred thousand white cells disappear to the point of a leucopenia. In a short time, however, the spleen gradually increases again in size, the white cells increase in number, the red cells decrease and the patient is a physical bankrupt.

In the Mayo Clinic in nineteen cases of this class the patients were splenectomized after the blood picture had first been brought to normal by the use of radium, x ray and benzol. All patients recovered but thus far we have no knowledge of the end result.

The leucemic spleen is not adherent and after reduction by radium is easily removed. The removal of the spleen in cases of cirrhosis of the liver is justified on the theory that the spleen stimulates the liver to overactivity and to excessive hemolytic power. It is well established that the liver destroys bacteria and protozoa and detoxicates poisons brought to it from the portal circulation. In portal cirrhosis the liver is apparently exhausted and unable to eliminate all the poisons directed to it by the spleen, and there is an ultimate formation of connective tissue about the portal radicals. The spleen, which is always enlarged in portal cirrhosis, suggests that the source of the poisons is in the spleen and, furthermore, splenectomy improves the condition of the patient.

TECHNIC OF SPLENECTOMY.

The removal of the spleen is not a difficult operation. A median incision, or one to the outer edge of the left rectus muscle down to the peritoneum, four to five inches long, is made and, if necessary, supplemented by a transverse incision through the rectus. The peritoneum is opened. The intestines are pushed aside and the spleen exposed. The liver, the gallbladder and the appendix are examined. Adhesions when present are stripped with the fingers or clamped and ligated.

After lifting the spleen out of its bed, a large gauze pack, as suggested by Balfour, is introduced into the space formerly occupied by the spleen. This will aid materially in the checking of all oozing points and at the same time support the spleen. The spleen is elevated and drawn toward the midline and the pedicle ligated. Care must be taken not to include the tail of the pancreas in the ligature. This can be avoided by isolating the arterial and venous branches in the pedicle and ligating them separately. If the procedure is found inadvisable, ligation *en masse* by two clamps is easily carried out.

In cases where the splenic adhesions are excessive, the liberation is at times followed by profuse venous bleeding. This bleeding can be controlled in three ways: 1, ligation; 2, clamping the bleeding mass and leaving the clamp *in situ* for three days, then loosening it for about twelve hours, and if no oozing follows, the forceps are removed; 3, the placing of a gauze pack, as suggested by Balfour, and leaving it in place for a few days.

In pernicious anemia the spleen is removed without difficulty. In hemolytic jaundice the spleen is at times very large, but the operation for its removal is without danger. Greater operative risk is encountered in cases of splenic anemic and in hepatic cirrhosis and particularly in leucemia, since the blood of a leucemic patient possesses less than the normal power of agglutination.

Blood transfusion preliminary to splenectomy is a therapeutic remedy of great value by: 1, improving the impoverished and diminished quantity of the blood; 2, by toning up the system and preparing it for the shock of the operation; 3, by gauging the effect of the transfusion on the health of the patient.

When a patient responds favorably to two or three transfusions prior to operation, the removal of the spleen will probably effect a cure. On the other hand, if no improvement follows repeated transfusion, splenectomy may be of no value. Considering the great quantity of blood present in the spleen, its removal necessarily withdraws from the patient a volume of blood which should be replaced by post-operative transfusion. The usual amount transfused is from 500 to 750 c. c., and I consider whole blood, as nature has provided, preferable to modified, medicated blood. Changes in the blood picture following splenectomy were studied and recorded by Pearce, of Philadelphia, and his coworkers. There is a slow progressive anemia which appears soon after removal of the spleen and reaches its height between the fourth and sixth week and then the blood gradually reaches normal about the fourth month, but the hemoglobin continues to increase up to the tenth

month. The white cells show polymorphonuclear leucocytosis soon after operation and then gradually fall to normal at about the fourth month. There is also a transient eosinophilia, but no increase in the lymphocytes was observed.

The postoperative course of splenectomized patients is equal to that of other major abdominal operations. This depends mainly on the disease and the condition of the patient at the time of the operation. If a patient is brought to the operating table as a last resort, very little can be expected, unfair advantage is taken of the surgeon, and surgery is reflected upon when the result is unsuccessful. Timely surgical interference, after brief medical treatment has failed to improve or cure, will bring gratifying results to both patient and physician.

HORATIO C. WOOD.

By HENRY BEATES, JR., M. D., Sc. D.,
Philadelphia.

By the death of Professor Horatio C. Wood the medical profession and mankind in general have suffered an irreparable loss. His life was an example of sincerity of purpose, diligence, honest endeavor and justice, and an exceptionally powerful influence for the uplift, growth and development of those sciences with which he was identified. Endowed with an unusual mind and insatiable in the acquisition of knowledge, the ever conspicuous power and faculty of learning were demonstrative of his great intellect. Indefatigable as an investigator, utilization of time and opportunity found him ever active in the study and solution of problems presented by the various natural sciences to which his life was dedicated.

The eagerness with which he engaged in study, a conspicuous characteristic, is illustrated by the following incident that occurred when a mere youth: Visiting the Philadelphia Academy of Natural Sciences, he stood before a locked cabinet containing specimens in which he was deeply interested, and being unable to handle and examine them, his disappointment found expression in tears. The great Leidy passed by and, noticing the distress of the youthful Wood, inquired the cause. Being informed and doubtless recognizing the impulses of genius, he had the cabinet unlocked and the specimens placed at the student's disposal.

Dr. Wood was an enthusiastic student of botany. In 1860, when but nineteen years of age, he presented his first scientific paper, Contributions to the Carboniferous Flora of the United States. From then until 1873 fourteen papers, each of which was an authoritative classic, appeared in the *Proceedings of the Academy of Natural Sciences*, *American Philosophical Society*, *Quekett Microscopical Club Journal*, *American Journal of Science* and the *Smithsonian Institute*. In 1872 the Smithsonian Institute published Dr. Wood's monograph *The*

Fresh Water Algæ of North America. This paper contained nineteen colored and two uncolored plates prepared from 360 original microscopic drawings which for accuracy of detail and perfection are unsurpassed. It remained the authoritative work on this subject for twenty-five years.

The following botanical papers may be mentioned as demonstrating Dr. Wood's phenomenally acute powers of observation: *Life History of Some Siphonaceous Fresh Water Algæ*; *Manner in Which Schizomeris Leibleinii Produces Its Zoospores*; *New Species of Desmids*; *New Species of the Genus Siroisiphon*, the *S. lignicola*, *S. phloiophilum*, *S. disjunctum*.

Entomology also engaged his attention during these years, and his achievements in this branch of science culminated in fourteen papers characterized by that thoroughness and masterful research which stamped each as an authoritative contribution and an acquisition to knowledge. Of these studies, which want of time prevents naming, that entitled *The Myriapoda of North America* was published in the *American Philosophical Society Transactions* in 1865. It was a brochure of 112 pages—with sixty-one figures in the text and three plates. The drawings, true to nature, were exponent of his skill. The excellence and reliability of his work was recognized by Louis Agassiz, who in 1865 headed a large naturalizing expedition to Brazil and after his return wrote the following letter to Dr. Wood:

DEAR SIR:

While in Brazil I have collected a good many myriapods in every part of the Empire visited and I will gladly put the whole at your service as soon as the specimens can be picked out, but I cannot say how soon this will be possible as I cannot make a beginning with the arrangement of my collections before I can secure the means of buying about 5,000 gallons of alcohol to carry the work through.

Very truly yours,

AGASSIZ.

Dr. Wood was an indefatigable worker. He would frequently concentrate his mind upon the subject in hand for thirty consecutive hours, then relax and indulge in uninterrupted sleep for from twelve to eighteen hours, when his insatiable thirst for knowledge found him again active in the pursuit of investigation and discovery, with that intensity of interest and painstaking care in observing the minutest details which crowned his labors with phenomenal success. Profound learning necessarily established a high plane from which to observe conventional standards of achievement, enabling Dr. Wood to enter his chosen profession of medicine with a mind exceptionally well informed and an intellect of superior power.

As professor of botany in the auxiliary medical course of the University of Pennsylvania, his ability as a teacher was highly cultivated, and later his occupancy of the chair of materia medica and therapeutics in the major faculty of medicine constituted one of the strongest and most influential of the then famous centre of medical education. He was a brilliant and impressive lecturer and a teacher of great renown.

His career in the natural sciences rendered him extremely alert in recognizing the inevitable consequences of cause and effect. He was painfully con-

scious of the imperfections and limitations of empirical medicine, and the measure thereof found expression in the fearless manner in which, then almost single handed, he entered the arena in a struggle having for its aim the establishment of physiological or rational medicine upon a firm and scientific basis. With an open mind ever alert to recognize and acknowledge truth, he did not belittle the knowledge of means to end that empirical medicine had established, but sought to add thereto elucidation and explanation. His sincere willingness to entertain and accept demonstration of mistake or error was parallel with his eagerness and desire to guide and instruct and guard against error wherever and whenever encountered, and the measure of his true greatness.

To Professor Wood belongs the distinguished honor of having been a pioneer in establishing the epoch of rational medicine. The courage of conviction that found him alone championing rational medicine, therapeutics based upon knowledge and logical conclusion, was conditioned upon his recognition of the defects of empirical medicine. From the first edition of his epochmaking treatise on therapeutics, published in 1874 and antedating that of Lauder Brunton by ten years, of which fourteen editions were printed and served as a model for textbooks on therapeutics in European countries as well as the United States, the following quotations from the preface serve to emphasize the firm foundation upon which he stood: "There are a number of excellent treatises upon materia medica and therapeutics, yet in various attempts at original research as well as in the ward and lecture room of the hospital I have keenly felt the want of something more. The old and tried method in therapeutics is that of empiricism or if the term sounds harsh, of clinical experience. The best possible development of this plan of investigation is to be found in a close and careful analysis of cases before and after the administration of a remedy, and if the results be favorable the continued use of the drug in similar cases. That very much has been thus accomplished it were folly to deny. Therapeutics developed in this manner cannot rest however upon a secure foundation. Looking at the revolutions and contradictions of the past, listening to the therapeutic Babel of the present, is it a wonder that men should take refuge in nihilism and, like the lotus eaters, dream that all alike is folly—that rest and quiet and calm are the only human fruition? A primary knowledge of the end to be accomplished, and a secondary acquaintance with the instruments are a necessity for human effort and until the sway of this law is acknowledged by physicians, medicine can never rise from the position of an empirical art to the dignity of applied science. The work of the therapist is with the second portion of the law. Evidently, it is his special province to find out what are the means at his command, what the individual drugs in use do when put into a human system." Thus did this champion and pioneer of rational medicine enter the arena of controversy and withstand the attacks of relatively ignorant and emotional antagonists who sought by all means available, social, financial and political, to

prevent scientific investigation and the establishment of the era of rational medicine.

Animal experimentation was a *sine qua non* which was most bitterly opposed. No less an authority than the famous Niemeyer, an authority however in another sphere, asserted that experiments made with medicaments upon lower animals or upon healthy human beings have as yet been of no direct service to our means of treating disease, and that a continuance of such experiments gives no prospect of such service. The antagonists asserted that medicines did not affect lower animals as they did human beings. Apparently the contention was well taken, but Dr. Wood demonstrated that while apparently this was true, in reality it was erroneous and a misinterpretation. He proved that while it required as much morphine to kill a pigeon of a pound weight as to destroy a man, it was not a different action but on the contrary an identical one, the seemingly different effects being dependent upon varied degrees of susceptibility, and that the *modus operandi* was identical. This physiological law or truth Dr. Wood further demonstrated by a study of atropine. An animal which may be exceedingly sensitive to the spinal action of atropine in contradistinction to that of its effects upon the conducting fibres, the nerve trunks, will result in convulsion on the one hand and paralysis on the other. This law makes understandable why so many drugs seemingly exert an antagonistic action. Dr. Wood, by conclusively demonstrating that degree and quality are two separate and distinct things and should never be confounded, successfully combatted the efforts of ignorance and emotionalism to make it a crime to pursue scientific research. What may properly be designated the *opus major* of Wood, the achievement of having instituted an epoch in medicine characterized by the relinquishment of the empirical and the adoption of the rational and of establishing an era conspicuous for achievements in preventive as well as curative medicine, is of itself sufficient to place his name side by side with those of the immortal Hippocrates, Galen, Sydenham, Hunter, Lister, Laennec, Jenner, Pasteur, and Koch.

In 1810 Majendie, studying the effects of nuxvomica, recognized the vital importance of knowing how medicines affected the human system, but to Horatio C. Wood belongs the credit of having brought to the recognition of the medical world the necessity of adopting rational medicine as the one essential means of acquiring that skill and art in the prevention and treatment of disease upon which humanity depends.

Dr. Wood consecrated himself to medicine. In 1869 he made his famous experiments upon himself with American grown cannabis, the details of which appear in his work on therapeutics. The following year his first paper on the Physiological Action of Drugs was published in the *American Journal of the Medical Sciences*. His studies of the action of veratrum viride led to its adoption in practice by clinicians generally. In 1871 Dr. Wood's papers treating of the physiological action of amyl nitrite were published. Two years previously Lauder Brunton published his paper which set forth the value of amyl nitrite in angina pectoris, but the

contribution of Dr. Wood was the first description of the physiological action of the drug upon the nervous system. His investigations of chloroform, ether and other anesthetics are so well known that mention only is necessary. These results were published in 1890 and the following year found him honored with being selected to make the principal address before the general session of the International Medical Congress (at Berlin). These studies have probably been responsible more than the work of any other scientist for the general adoption of ether as an anesthetic by the entire surgical world. It was while pursuing the studies of anesthetics and the treatment of their toxic effects that Dr. Wood discovered the value of strychnine as a respiratory stimulant and its importance in averting threatened death.

Of 5,000 scientists present at the Berlin Congress the Duke of Bavaria, a physician, selected and entertained twenty-five who were noted for exceptional achievements. Of these Professor Wood was one and when about to be seated the Duke removing his crown placed it upon Dr. Wood's head and further honored him by requesting him to occupy the chair *pro tem*. Thus Professor Wood was Duke of Bavaria for almost an hour.

In 1903 Dr. Wood represented the United States Government at the International Conference held at Brussels for the purpose of unifying the more important preparations of the various *Pharmacopæias*. Early in its session this conference became so involved in an acrimonious dispute as to the proper percentage of alcohol to be used in making tinctures that the whole usefulness of the meeting was seriously threatened. Dr. Wood, by his personality and well known advocacy of justice and right, succeeded in convincing the delegates of the foolishness of quibbling over minor details and they finally adopted the present regulation for ten per cent. tinctures and various other standards which are recognized by the *Pharmacopæias* of practically all civilized nations. This busy clinician, investigator, teacher and author published his textbook on *Nervous Diseases and their Diagnosis* in 1887.

Of 240 medical papers each one of which was a classic and an addition to the knowledge of the science and art of medicine, the treatise on thermic fever or sunstroke has especial value. Published in 1872, it was accorded the Boylston Prize. What this work has contributed to the saving of thousands of lives annually, is testimony of one of the great services this man of genius has accorded to many. His investigations of fever culminated in a work of 250 pages which was published by the Smithsonian Institute in 1880. It is a monument to his learning and a most valuable contribution to medical science. Dr. Wood discovered the alkaloid hyoscyne while studying the effects of hyoscyamine and in 1885 demonstrated its value for certain nervous diseases.

His researches in experimental pharmacology, physiology and pathology embody more than fifty contributions to the science and art of medicine. Twelve conscientiously elaborated subjects of medical jurisprudence and toxicology were contributed from the years 1873 to 1899. As a clinician, his studies of pathology, medicine and therapeutics

comprise 139 papers which for originality and profundity of learning are invaluable. Thirty-six published lectures and addresses appeared in various journals during the years 1874 to 1900 and extended his beneficial influence throughout the continent.

Nine magazine articles from the year 1872 to 1879 brought to the lay mind information and knowledge which proved of great value in securing popular cooperation with efforts instituted by the profession for the betterment of standards of medical efficiency. In 1875 there appeared in *Lippincott's Magazine* an article contributed by Dr. Wood entitled Medical Education in the United States. This paper brought to a crisis the agitation which had been active for many years concerning this matter, which was and is of such vital importance to the profession of medicine as well as the greatest and highest interests upon which human welfare is conditioned. It caused radical changes in the medical department of the University of Pennsylvania, and indirectly compelled other colleges of medicine to reform their curricula. It advocated State Board examinations and was a powerful influence for the establishment of the legal supervision of the qualifications and rights to practice the healing art.

In 1889 Yale University conferred upon Professor Wood the degree of LL.D. The occasion was made an opportunity by Dr. Wood to use his influence in promoting and intensifying interest in higher medical education. The title of his address, The Medical Profession, the Medical Sects, the Law, emphasized the necessity of demanding for the doctorate men of proper preliminary education and the administration of an ample curriculum. The too commonly encountered unfitness of clinicians upon whom colleges had conferred the medical degree and the fearful consequences he emphasized by the astounding statement that the horrible disasters of the Johnstown flood were insignificant when compared with those resulting from the ill prepared and unqualified practitioner. So strongly was Dr. Wood convinced of this seriously defective but then prevalent system of medical education that the comparison was unhesitatingly presented to the interested audience with that vehemence which always characterized his advocacy of higher ideals.

It is the habit of action that individualizes man and imparts special qualities to his character. That "nature never rhymes her children nor makes two men alike" is a fact that explains why men of genius constitute a centre from which emanate influences for either good or evil which powerfully modify the lives of all within their range. That Dr. Wood was keenly alive to this great truth is made manifest by his definition of character: "Character is the established equilibrium existing between the emotional, the intellectual and the volitional." To establish and possess that equilibrium is an achievement which few attain. It taxes to the utmost the noblest and best qualities with which a man is endowed, and that Dr. Wood was ever alert to so do was evidenced by his every action. Once while in conversation he suddenly stooped down and caught a large roach that was crossing the floor and, holding it in his hand, fondled it. Being asked why, his reply was that to master a foundationless dislike of

anything harmless was invaluable and when it caused one to overcome empty prejudices it contributed to the usefulness of being and did much to give force to one's influence for the betterment of fellow man.

Dr. Wood was profoundly conscious of the value of time, and as a superficial glance into his active life shows, every moment was advantageously occupied. As an example of untiring and continual work he stands preeminent, and the fundamental principles underlying his achievements are well shown by the subject of his inaugural address before the trustees, faculty and student body of the University of Pennsylvania when as professor of materia medica and therapeutics his wonderful career in that capacity began. He urged upon every one that a definite object in life is the goal for which to strive, and that substantial progress is conditioned upon a thorough mastery of each involved factor. In that manner by which he had the happy faculty of impressing great truths upon the minds of his pupils, he drove home these principles by quoting from *Mother Goose*, how "leg over leg the dog got to Dover," and all who were privileged to hear him proclaim that the dream of his life was to become a professor and that by a conscientious mastery of minute and upbuilding details the goal was reached, were doubtless stimulated to emulate the great teacher and strive to do their best.

As Emerson so impressively states, character is the moral order seen through the medium of an individual nature. An individual is an enclosure. Time and space, liberty and necessity, truth and thought are left at large no longer. All things exist in the man tinged with the manners of his soul. With what quality is in him he infuses all nature that he can reach, nor does he ten to lose himself in vastness. He animates all he can, and he sees only what he animates. He encloses the world as the patriot does his country, as a natural basis for his character and a theatre for action. A healthy soul stands with the just and the true as a magnet arranges itself with the pole, so that he stands to all beholders like a transparent object between them and the sun, and who journeys toward the sun journeys toward that person. He is thus the medium of the highest influence to all who are not on the same level. Thus men of character are the conscience of the society to which they belong. To the honor and memory of the first president of the American Therapeutic Society may be ascribed the consummation of a life conspicuous for moral, intellectual and physical excellence, the influence of which for betterment will continue on and on. His example will ever serve the thousands whom he influenced as a guide and stimulus for right living and constitute a power for good in the uplift of humanity as enduring as time.

Analysis of Blood of Insane Patients.—Paul G. Weston (*Archives of Neurology and Psychiatry*, February, 1920) states that the blood of epileptic, dementia præcox and manic depressive patients shows no deviation from the normal content of total nitrogen, nonprotein nitrogen, uric acid, urea, creatinin, creatin, glucose, chlorine or calcium.

EVOLUTION OF MODERN MEDICINE LEADING TO GROUP DIAGNOSIS.

BY HYMAN GOLDSTEIN, M. D.,

New York,

Assistant Medical Director and Pediatricist, New York Diagnostic Clinics; Visiting Physician, Home of the Sons and Daughters of Israel; Assistant Physician, Pediatric Clinic, Lenox Hill Hospital, O. P. D.

In reviewing the evolution of modern medicine three periods are noted:

1. Ancient: a, Prehistoric medicine before Hippocrates; b, classical or Greek and Roman medicine, 460 B. C. to 476 A. D.

2. Medieval: a, 476 A. D. to Paracelsus, 1493; b, philosophical medicine, 1493 to Pasteur, 1822.

3. Modern or scientific medicine, 1822 to the present.

The earliest historical fact in the healing art is that it was in the hands of the priests attending in the temples of certain deities. The earliest known physician lived in the third Egyptian dynasty about 4500 B. C. He had a temple erected in his honor on the Island of Philæ and was worshipped at Memphis. Engravings depicting surgical operations, dated about 2500 B. C., have been found, and also a vase of an Egyptian Queen of the eleventh dynasty containing dried drugs. In the edicts of Hammurabi, 2500 B. C., there are regulations for medical practice, rewards for success and punishment for failure. The first known surgical instruments were copper knives found in a tomb near Thebes, dating from about 1500 B. C. It is interesting to note how medicine was practised then in the different localities.

ANCIENT MEDICINE.

Egyptian Medicine.—The Egyptian physicians appear to have been specialists. According to Homer, they were particularly skillful in compounding drugs. They were familiar with the use of castor oil, opium, colchicum, gentian, squill and other drugs, which they usually compounded with excreta, blood, etc. The physicians were divided into three classes, as follows:

1. The lower class or military physicians.

2. The next upper class were the Pastophora, who studied the last six books (Hermatic) dealing with anatomy, pathology, pharmacy, ophthalmology and gynecology.

3. The highest class of physicians were the sages or soothsayers, who acquired their learning from the thirty-six Hermatic books of Thoth.

Models in gold or silver of the diseased parts (anathemata) were given by sufferers to priests who hung them before shrines, and later sold them to other invalids. Medicine as practised those days was largely sacerdotal.

Babylonian Medicine.—The people of Babylon were their own physicians, bringing all who were sick to the market place, where every passerby could stop and express his opinion, diagnose, and treat the case. Later on came the physician priest. Nearly every disease was attributed to the liver, and medicines were given internally to dispossess demons.

Jewish Medicine.—The sources of this knowledge are the Bible and Talmud. The Jews excelled

in anatomy and hygiene. They advocated the earliest operation of circumcision, and also described bubonic plague and syphilis. Medical education among the ancient Hebrews was very progressive.

Medicine of the Hindus.—This is a history of elaborate error. The Hindus, however, excelled in surgery, their cataract operation being used today. Susruta in the fifth century attributed the cause of malaria to the mosquito.

Chinese Medicine.—Medicine in China is the essence of conservatism. It has been practically stationary for thousands of years, and is now about on the level of European medicine in the thirteenth century. The Chinese still believe that the larynx opens up into the heart, the spinal cord into the testicles, and that the spleen and heart are organs of reason.

Japanese Medicine.—In medicine as in other sciences Japan has shown a remarkable capacity for assimilating European knowledge. Before 96 B. C. all her medical science was superstition and mythology. From that time to 700 A. D. it was that of the Chinese, when she began gradually to absorb outside ideas and to keep pace with European medicine.

Ancient Greek Medicine.—Medicine of ancient Greece is supposed to have originated with Æsculapius, the god of medicine among the Greeks, subsequently adopted by the Romans and usually said to have been a son of Apollo. He was worshipped in particular at Epidauris in Peloponnesus, where a temple with a grove was dedicated to him. The sick visiting his temple had to spend one or more nights in the sanctuary, after which remedies to be used were revealed in a dream. Those who were cured offered a sacrifice to Æsculapius. There were two sets of physicians of the temple, i. e., those who were priests of Æsculapius and Æsclepiadæ, who were physicians but not priests and who learned medicine from their fathers or foster fathers.
